Again, in your practice you will occasionally observe peculiarities in structure, which should be placed on record, such as polydactylism, polymastism, polyorchism, pseudo-hermaphroditism, etc. In all such cases, urge your patient to submit to examination by an anatomist, and if he declines, study the case in detail, look into the family history, and ascertain whether similar peculiarities are known among the relatives. But, before you publish your observations, inform yourself upon the literature of the subject. And this leads me to several further advisory suggestions: I should advise you to keep up your studious habits and not to "rush into print."

As for rushing into print, you may not know that the first serious disease which attacks the graduate is the publishing disease. He is soon seized with an absolute conviction that he is called upon to write an article which shall contain every fact known upon a given subject. I once knew a young graduate in medicine who decided to write a monograph upon the horse, This work was to contain every fact (discovered or undiscovered) about the equine species. I met him from time to time for several years, and saw the plan of this great epoch-making equine encyclopedia gradually dwindle down until the would-be authority published an extensive review of another person's paper on the rudimentary bones in the horse's leg, attaching his own name to the review, but inadvertently omitting the name of the original author and article. Now, gentlemen, do not, I beg of you, write an epoch-making monograph the first year after you graduate. The book-writing disease is one you are all subject to. It is, however, very amenable to treatment, and this is quite simple, although somewhat heroic. It consists in reading a few books which have been written by other men suffering from the same disease. Select any subject, however small, go to the surgeon-general's library and read every article you can find upon that subject, and in most cases, I believe, you will come to the conclusion that you will not publish your monograph until you have made a few original observations in that particular line and have something to say. Do not disgrace yourself and your Alma Mater by becoming a bibliographic kleptomaniac.

In your medical writings, never use a scientific word unless you know its exact meaning and its application to the subject you are discussing. Scientific names are necessary evils. In the writings of one who knows their exact meaning, they are useful; but when used in a loose and inexact way they show poor taste, reminding the reader of Browning's lines:

> As when in certain travel I have feigned
> To be an ignoramus in our art,
> According to some preconceived design,
> And happed to hear the land's practitioners,
> Steeped in conceit sublimed by ignorance,
> Prattle fantastically on disease,
> Its cause and cure—and I must hold my peace!

in the letter of "The Arab Physician."

Speaking for my own specialty, I regret to say that fully one-third of the articles on medical zoölogy which I have found in the medical journals are unintelligible to the specialist—whatever may be the ideas they convey to the practitioner—largely because of the reckless use of technical terms.

It is always a good plan to submit your articles to a specialist or to your colleagues for criticism before you send them to press. Another good plan is to place your manuscript—especially if it is your first effort—under lock and key, from sixty days to sixty years (so that the ideas may not escape), the time of confinement varying directly in proportion to the importance you attach to the views you advance. If you feel convinced that your ideas are destined to revolutionize modern medical thought, sixty years is rather a short period of imprisonment for your manuscript; while if, in your early articles, you "decide" that "no such disease exists as hydrophobia," that "the claims which the advanced members of the profession make for antitoxin are absurd," that "Harvey did not use vivisection in studying the circulation of the blood," or if you suddenly "come to the conclusion that "Koch's discovery of tuberclin is useless" and that "no good has ever come from animal experimentation," then imprisonment for life, or even capital punishment, would not be too severe treatment for your manuscript, and possibly for the author also.

Be careful about your language in writing. It is always better to say that you believe an author is "in error" (let it be Pasteur, Koch, Claude Bernard, Laboulbène, Blanchard, Welch, Sternberg, or Salmon) than to say that his "statement is false." In either case the reader will simply take your assertion as meaning that there is a slight difference of opinion upon the subject in hand, and the more modestly and delicately you express your own view on the subject, the more weight your article will have with those who read it.

So much for your opportunities to aid zoology. I now wish to make a suggestion concerning "bread-pills" from the standpoint of a non-practitioner and occasional patient. It is generally supposed by young graduates that it is always best to look wise and administer "bread-pills" in case you are in doubt as to diagnosis and treatment. To make this rule absolute is, I believe, a serious mistake. I maintain that bread-pills are perfectly justifiable, but that they have their place. In many cases they may work upon the imagination and thus lead to speedy recovery, while there is a chance that a more heroic treatment might result otherwise. There are some people, however, who believe that an honest confession of ignorance and a willingness to study the case are occasionally better than a show of knowlege; and if any of you ever enter abstract science, this is the first lesson you will be obliged to learn. I would therefore respectfully suggest, from the standpoint of certain patients—possibly the minority—that you study human nature and take into account the temperament, as well as the temperature of your patient; that you keep a large supply of bread-pills on hand; that you give them freely, though not free, to all patients who need them, but give to yourself, at the same time, assurance and vows of faithful study of the case. You should educate your patients, as well as yourselves, to the truth that it is often more important to decide what to proscribe than what to prescribe.

What I have said thus far applies to the entire class, and now I have a closing word of advice to give to about five or ten per cent. of the class, *i.e.*, experiment. Advance in medicine is suggested by observation; it is made by experimentation. All practitioners are capable of observing, some are capable of experimenting. Certain conditions, however, must be complied with before you essay experimentation. I refer, first of all, to a thorough knowledge of the literature upon the subject you wish to investigate, so that you may know the successes and failures of former investigators in that particular line. In the next place, perform your first experiments under the direction of some experienced investigator; and finally, and most important of all, hold fast to the view defended by the humane profession you have just entered, *i.e.*, that a human life is worth more than the lives of all the stray dogs within the field of your observation. Establish results by animal experimentation before you try theories on human beings, and, if a short-sighted, sentimental, and medieval policy at the end of the nineteenth century results in legislation which will seriously hamper or prevent such experimentation in one part of a civilized country, move to another place, rather than risk human lives in experiments which can be performed elsewhere upon the lower animals.

Finally, gentlemen, on behalf of the faculty I desire to thank you for your faithful work these past four years and to wish you all the success possible in your practice. While in practice, do not lose sight of the fact that the principle of the "survival of the fittest" holds in the medical profession, as well as in the "origin of species." If you wish to survive as one of the fittest, it must be by an honorable and professional "struggle for existence." In the time of your successes and reverses do not, however, forget your Alma Mater, for she will always have for you a word of welcome, of comfort, and of praise.

SOCIETY PROCEEDINGS.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held at Hot Springs, Va., September 8, 1896.

DR. A. R. ROBINSON of New York, the President of the Association, delivered the annual address. After welcoming the members he announced the death, since the last meeting, of one of the Society's oldest, ablest, most active members, Dr. Edward Wigglesworth of Boston,

and spoke of his genial and courteous bearing, of which the members had so distinct a recollection. To some he was a well-proven friend, and to all an honored and admired colleague, whose absence from the Society's meetings will be sadly felt. The question of the rightful territory of the dermatologist was then discussed, and the effort was made to show to the general profession that cutaneous diseases are much more numerous and complicated than is usually supposed, while some are dangerous to the subjects thus afflicted. It would seem, therefore, that a more prominent position should be accorded dermatology in the college curricula.

In discussing the President's address, Dr. WHITE said that for several years Harvard University has required study in dermatology, both theoretically and practically. The examination is rigorous, and at times excludes from the degree.

Dr. DUHRING thought notice should be taken of the advances which had been made in a few of the universities. In the University of Pennsylvania the student is marked on the same basis as in anatomy and surgery.

Dr. JACKSON said that for several years Columbia College students had been required to pass an examination in diseases of the skin, and after the present year would be required to take a course of twelve lessons yearly. Dr. Morrow said that six years ago instruction in dermatology was not compulsory in any college in this country. The statements of the speakers were, therefore, of much satisfaction.

G. T. JACKSON, M.D., of New York, presented a paper entitled

PAGET'S DISEASE OF THE NIPPLE,

and described a case of a woman, fifty-two years of age. The disease developed from what seemed at first to be a simple dermatitis into a clear case of Paget's disease, within fifteen months. No cause was discoverable. The breast was amputated by Dr. B. F. Curtis, and the patient made a good recovery. After nine months the patient was seen again, and showed no symptom of return of the disease in any way. Histological examination of the removed gland showed the presence of a non-cancerous tumor in the breast, which the pathologist, Dr. Ely, thought might have been the origin of the disease of the nipple. On the second visit of the patient it was found that she had a tumor in the remaining breast. Dr. Jackson urged the advisability of amputation of the breast in all cases of Paget's disease as soon as a positive diagnosis was arrived at. He did so on account of the exceeding rebelliousness of the disease to treatment and its proneness to the development of cancer.

Dr. FORDYCE opened the discussion by differing from the views upon the pathology as given in the report of the pathologist who had studied Dr. Jackson's case. It would seem that a fibrous growth existed in the breast before the areolar disease showed itself. We are led to believe that the disease begins in the epidermic cells, results in a peculiar degeneration in the protoplasm, and extends along the galactiferous ducts.

Dr. BOWEN also disagreed with the pathologist's views that the skin lesions were secondary if this is to be regarded as a true example of Paget's disease.

Dr. DUHRING said the skin affection was here practically identical with eczema in the early stage. If seen some years later an entirely different diagnosis might be made, the eczema-like element having disappeared or become overshadowed by the epitheliomatous development. He had suggested the designation *Eczematoid epithelioma* since almost all cases eventually became epitheliomatous.

Dr. WHITE did not think the case described could be looked upon as Paget's disease, either clinically or pathologically. Excision of the breast should always be advised in Paget's disease, if improvement does not take place promptly from the use of ordinary remedies.

Dr. ROBINSON thought there might here have been a fibroma with nipple eczema as an accidental combination. He did not see that any connection had been shown between the two processes.

L. A. DUHRING, M.D., of Philadelphia, presented

A PATHOLOGICAL AND CLINICAL CLASSIFICATION OF THE DISEASES OF THE SKIN.

A printed table showed the diseases arranged in nine groups. The classes made were: (1) Anemias; (2) congestions; (3) inflammations; (4) hemorrhages; (5) neuroses; (6) hypertrophies; (7) atrophies; (8) new growths; (9) diseases of the appendages of the skin, divided into disease of (*a*) the sweat glands; (*b*) sebaceous glands; (*c*) hair follicles, and (*d*) nails. The structures composing the appendages of the skin, especially the follicles, hair, and nails, are subjected to such varied forms of disease that it is found eminently proper and useful to bring them together. Differing from the writer's previous work in the same direction there is an omission of all etiology in the make up of this classification which is based rather on pathology, histopathology, and anatomy.

Dr. WHITE did not see how we could ignore the etiological element in a system of classification. It seemed to him more important than an anatomical classification. The position accorded various diseases was criticized, as was the entering of the same disease under two different classes, which was apt to confuse the student.

Dr. MORROW thought all admitted that an etiological would be the ideal classification, and it seemed a step backward to ignore etiology entirely. He regarded the task of making a satisfactory classification impossible.

Dr. ALLEN thought it a reproach to American dermatology, and to the Association, that we had to rely, in our work, upon an alphabetical list of skin diseases. The argument that because a satisfactory classification could not now be made none should be attempted was not sound. There probably never would come a time when views regarding the nature of diseases would not be in a state of transition. He hoped Dr. Duhring would persist in his efforts to give as good a classification as is now possible. Dr. Robinson said that Dr. Duhring's original classification was the more useful. The attempt to arrange the diseases in this manner was correct, and as good a basis as was at our disposal at the present time.

J. A. FORDYCE, M.D., of New York, reported a case of

PECULIAR AFFECTION OF THE MUCOUS MEMBRANE OF THE LIPS AND MOUTH,

in which the mucous membrane of the lips and inner sides of the cheeks was the seat of numerous, closely aggregated milium-like bodies.

The affection began two years previously and had progressed in a symmetrical manner since that time.

On superficial examination, the normal vermilion-color of the affected region seemed to have been replaced by a light yellow tint. When the parts are put on the stretch the individual lesions composing the patch were plainly visible.

A portion of tissue from the oral cavity, excised for microscopic examination, showed a degenerative process in the protoplasm of the epithelial cells. The muciparous glands were not involved.

A colored drawing and several photomicrographs were shown in connection with the report.

DR. HARDAWAY of St. Louis, presented the photographs of a case of

ARSENICAL PIGMENTATION,

Distributed over the anterior and lateral aspects of the trunk and extremities. In another case the lower portion of the thighs, and the anterior of the trunk were exempt.

DR. ALLEN of New York, presented a new comedo extractor, with pustule lance attached. The advantage being that one instrument, instead of several, was sufficient for the various steps in acne work. By a forceps-like device, lateral pressure and a squeezing or massage of the skin could be carried out.

J. MCF. WINFIELD, M.D., of Brooklyn, read the next paper, entitled

A FAVUS-LIKE ERUPTION OF THE ORAL MUCOUS MEMBRANE, CAUSED BY THE ASPERGILLUS NIGRECEUS.

The patient was a woman twenty-seven years of age, who had never had any serious illness. Two weeks before she had noticed "a small ulcer" in the middle line of the roof of the mouth. It occasioned no pain or discomfort only when irritated by some hard substance in eating. The patch slowly increased and another formed in front of it, and others subsequently developed. An antisyphilitic course had shown no good results. Antiseptics had also been applied. Favus was suspected. When first seen by the reporter there was an edematous, lumpy patch on the left side of the mouth, from the incisors to within an inch of the soft palate, with outlying smaller patches. A firmly attached dirty-yellow deposit covered the areas. Parts were grayish brown, the surrounding tissues were edematous. The picture suggested favus, or a beginning tuberculosis. The microscope disclosed a fungus differing from the achorion. The fibers showed no tendency toward fission. The manner of punctifying shows that the fungus did not belong to the oïdium but to the ascomycetous genus. It grew rapidly in cultures. Treatment directed to the prevention of the plant from bearing fruit, by applying peroxid of hydrogen in strong ethereal solution, proved effective. The case, so far as the writer could discover, is unique. The cause was supposed to be eating moldy cheese, for which the patient had a decided liking.

Referring to the differences in culture, the speaker said thrush gives a thin film, the trichophyton a cottony growth, and the *Aspergillus nigreceus* a grayish-brown mold.

DR. FORDYCE thought the case unique as well as interesting.

DR. DUHRING did not remember to have seen such a case. He asked if the membrane was adherent or easily removed.

DR. WINFIELD replied that considerable force was required, and caused slight bleeding.

In the morning session of the second day a general discussion was opened by J. C. WHITE, M.D., of Boston, upon the subject

WHAT EFFECT DO DIET AND ALCOHOL HAVE UPON THE CAUSATION AND COURSE OF THE ECZEMATOUS AFFECTIONS AND PSORIASIS?

The speaker said that at the International Congress, from which he had just returned, this important subject had scarcely been touched upon, one paper having been read upon the influence of vegetable diet in psoriasis. Observations have been so inexact that conclusions cannot be drawn from them. It is well known that there are disturbances of the skin which result from errors in diet, but they are, for the most part, fugitive and idiosyncratic. Food containing toxic properties is well illustrated in scorbutus and pellagra. In infancy, under the simplest and most uniform diet known, eczemas are prevalent and extremely obstinate. Eczema is occasionally provoked and kept up by acid fruits, but no specific articles of food were recognized as bearing upon the production of the disease. In eczema, the diet should be the same as in all ordinary inflammations. He does not recognize the influence of any so-called diathesis, and hence would deny the efficacy of systems of diet in eczema based upon an assumed curative effect in such imaginary diatheses.

(To be continued.)

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDED AUGUST 31, 1896.

PERRY, T. B., Passed Assistant Surgeon. Detailed to represent Service at meeting of American Public Health Association; August 24, 1896.

VAUGHAN, G. T., Passed Assistant Surgeon. Detailed for duty in connection with Immigration Service at Philadelphia, Pa.; August 25, 1896.

COBB, J. O., Passed Assistant Surgeon. When relieved from duty at Cincinnati, Ohio, to proceed to New York for duty; August 25, 1896.

STIMPSON, W. G., Passed Assistant Surgeon. Relieved from command of Service at Port Townsend, Wash., on arrival of Passed Assistant Surgeon S. D. Brooks; August 25, 1896.

SPRAGUE, E. K., Assistant Surgeon. When relieved from duty at New York to rejoin his station at Boston, Mass.; August 27, 1896.

CUMMING, H. S., Assistant Surgeon. When relieved from duty at Norfolk, Va., to proceed to Evansville, Ind., for temporary duty; August 25, 1896.

GREENE, J. B., Assistant Surgeon. To proceed from Baltimore, Md., to Cleveland, Ohio, for temporary duty; upon completion of which to rejoin station; August 25, 1896.

ORIGINAL ARTICLES.

REPORT OF THIRTEEN CASES OF MULTIPLE NEURITIS OCCURRING AMONG INSANE PATIENTS.[1]

BY E. D. BONDURANT, M.D.,
ASSISTANT SUPERINTENDENT OF THE ALABAMA BRYCE INSANE HOSPITAL, AT TUSKALOOSA.

THE inflammatory-degenerative changes, which, occurring in the peripheral nerves, are generally described under the name of "neuritis," may be especially active in the nerve-sheaths and connective-tissue framework—"interstitial neuritis,"—or have their chief location in the nerve-fibers—"parenchymatous neuritis"—or, as is most often the case, may involve both the neural and connective-tissue elements—"diffuse neuritis." The causes of neuritis are many and varied, and, used as a basis of classification, give rise to a number of more or less easily recognizable clinical varieties of the disease, the most important being:

(1) The neuritis occurring as a result of direct injury to the nerve-trunk—wounds, blows, pressure, as from sleeping on the arm, from dislocation of bones, from tumors. (2) That form resulting from exposure to cold. When the trunk of the seventh cranial nerve is involved, as is often the case, we have here a familiar form of facial paralysis. (3) The forms resulting from direct extension to adjacent nerves of the infection of bacterial diseases, as pneumonia, diphtheria, tuberculosis. (4) Those forms due to the presence in the blood of the poisons of these infectious diseases, especially syphilis, diphtheria, typhoid fever, malaria, variola, and tuberculosis. (5) The varieties resulting from introduction into the blood of toxic agents from without, as alcohol, arsenic, lead, opium. (6) The endemic or epidemic forms frequent in Asia and the islands of the Pacific, as the "kakke" of the Japanese and the "beriberi" of the Malay peninsula. (7) Certain forms affecting especially the cutaneous nerves and accompanied by trophic disorders of the skin in area supplied by the diseased nerve, of which herpes zoster is a familiar example.

Whatever the cause of the neuritis, or its pathological variety, if it involves a single nerve or a small group of adjacent nerve-trunks, it is called "simple neuritis"; if a number of nerves in different portions of the body are simultaneously affected, "multiple neuritis." The varieties referred to in 1, 2, 3, and 7 above are usually "simple"; those in 4, 5, and 6, are apt to be "multiple." To these rules, however, there are exceptions. Thus, the writer has seen one case of typical peripheral neuritis (or pseudo-tabes) due to pressure upon the lumbar and sacral nerves of a large aneurism of the abdominal aorta; on the other hand, general toxemia may cause localized effects, as has been observed in one case here, where, in consequence of the therapeutic employment of arsenic, a herpes zoster occurred. A simple neuritis is also apt to be interstitial; a multiple neuritis, parenchymatous.

Since some confusion exists in the minds of many as to the relation borne by the different forms of neuritis to one another, and as to the proper naming of the several forms, it may be well to state that "multiple neuritis," "peripheral neuritis," and "polyneuritis" are synonymous terms, and that "alcoholic neuritis," "malarial neuritis," "syphilitic neuritis," "pseudo-tabes," etc., are all forms of multiple neuritis.

At the Insane Hospital, during a period of ten years, ending February, 1895, there occurred not more than a half-dozen cases of multiple neuritis, and all of these, with two exceptions, were of the alcoholic or syphilitic variety, the exceptions being the polyneuritis in the lower extremities, due to compression of aortic aneurism, to which reference was made above, and a case occurring in a negro man, who, while much excited, stamped his bare feet upon the floor until both were much inflamed, a neuritis following as a probable result of the injury.

In February, 1895, a case of multiple neuritis developed in a white female patient without assignable cause, and in the past autumn and winter—from November, 1895, to February, 1896, twelve other cases of multiple neuritis occurred. These cases were distributed irregularly through the several wards and departments of the institution, four of them occurring in white men, eight of them in white women, one in a colored woman, the population of the Hospital numbering about twelve hundred.

[1] Read (by title) at the meeting of the Medical Association of Alabama, at Montgomery, April 21 to 24, 1896.

A brief memorandum of the thirteen cases is appended for reference:

I.—A white woman, aged thirty-two, imbecile, healthy, well-nourished. Without discoverable cause, a neuritis developed in nerves of lower extremities, extending to middle of thigh, the symptoms being pain, sensory perversions, muscular weakness and incoördination, becoming in ten days a complete motor paralysis of affected part, with inability to walk or stand and characteristic "foot-drop," trophic disturbances—some edema and a scattered herpetic eruption on legs—absence of patella reflex. There was in the beginning slight rise of temperature, restlessness, furred tongue, offensive breath, and some gastro-intestinal disturbance. After a month or two, muscular atrophy became marked, and in course of time the calves of the legs diminished to about half their former size. Electrical reactions at this time: Markedly diminished excitability to galvanic as well as to faradic current, without a typical reaction of degeneration. After remaining at a standstill for four months, patient began improving, and now (six months after attack developed) has partially regained power over muscles in the legs, although still unable to walk or to stand. She is slowly improving, and will probably recover entirely.

II.—White woman, aged forty-six, demented many years, well-nourished and in good bodily health, developed what was at first regarded as a malarial attack—chill followed by rise of temperature. A day or two later began complaining of pains in legs, with weakness, and became unable to walk. She showed the usual sensory disorders, absence of patella reflexes, muscular paresis, incoördination, etc., followed after a few weeks by atrophy of muscles of legs. She remained helplessly in bed for two months, then slowly regained use of the limbs, and now (five months after onset of attack) is practically well, although the legs are still smaller than formerly, and she is somewhat unsteady in her gait. Reflexes have not returned.

III.—White woman, aged forty-three, terminal dementia, physical health good. Had a "bilious attack" (or auto-infection fever) lasting a week, with nausea, anorexia, furred tongue, headache, offensive breath. She recovered entirely from this and remained out of bed a week; then began complaining of pains in her legs, of weakness, and of inability to walk. Soon grew unable to stand or to use limbs at all; feet and legs became edematous and intensely painful and hyperesthetic; patella reflex vanished; no fever nor constitutional disturbance. Some muscular atrophy supervened, and a typical reaction of degeneration could be obtained in affected muscles within a month from the time the disease appeared. After two months she began improving, and now (four months from onset of attack) is able to walk and suffers no pain. Still has some muscular incoördination and reflexes have not returned.

IV.—White man, aged thirty-five; epileptic since infancy, and mental faculties disordered for many years; anemic, emaciated, and nephritic. He took to bed with gastro-intestinal symptoms and a slight rise of temperature, followed by pain, sensory perversions and muscular weakness in legs, with loss of patella reflex. He was never entirely paralyzed, muscular atrophy was not marked, and after two months he was able to walk again. Reflexes are still absent after five months.

V.—White man, aged thirty-three; epileptic since childhood, imbecile and demented, but healthy and well-nourished. Without assignable cause, and without any pronounced constitutional disorder, legs became weak and unsteady, painful, edematous, and patella reflexes disappeared. He was unable to walk for several weeks, then slowly improved, and after two months was able to get about as usual. Muscular atrophy slight.

VI.—White woman, aged twenty-six; hysterical mania, with dementia. Health good, body well-nourished. Beginning with a mild auto-infection there was rise of temperature to 101° F. on second day, she developed pain and tingling sensations in legs, with muscular weakness and absence of reflexes. She remained in bed one week only, then became able to walk again, improved steadily, and in two months had practically recovered.

VII.—White man, aged thirty-eight. Chronic melancholia with dementia; anemic, nephritic, and poorly nourished. Neuritis developed in lower extremities without visible cause, the symptoms being pain, sensory disorders, weakness, absence of reflexes, etc., as in the other cases, together with some gastro-intestinal disorder. At this time (three months after onset) patient is partially recovered, but is in bed a part of the time and legs are weak and smaller than before.

VIII.—White woman, aged forty-five. Chronic mania engrafted upon a paranoiac disposition. Previous health good. After three or four days of malaise, rise of temperature to 100° F., gastro-intestinal disorder, etc., local symptoms of neuritis in nerves of legs and lower half of thighs appeared, with burning pain, sensation as of "ants crawling on legs," "as if legs were asleep," edema, tenderness, muscular weakness, etc. She was never entirely paralyzed, pain grew less after a few days, and she retained power of locomotion throughout, although showing a markedly ataxic gait. Patella reflex abolished. Later, distinct muscular atrophy and a partial reaction of degeneration were noted. Gradual recovery of power in legs and restoration of reflexes in five months.

IX.—White woman, aged thirty-three. Epileptic since childhood and demented for ten years. Previous health good. Underwent the "Flechsig opium treatment" for epilepsy—opium in slowly increasing quantity given for a month, suddenly withdrawn, and potassium bromid in large doses substituted. Fits stopped, but about two weeks after withdrawal of the opium, patient having for some days shown gastro-intestinal and

auto-infection symptoms, a neuritis developed in lower limbs, all symptoms more marked on one side than on the other. The pain was a prominent feature for several weeks, and, later, muscular atrophy became pronounced. After a month symptoms of neuritis developed in both forearms, and after this both foot- and wrist-drop were present. Reflexes abolished. Patient grew steadily weaker, emaciated, became stupid, lay in a semi-comatose state for days, had persistent constipation, furred tongue, sordes on lips and teeth, offensive breath, anorexia, no rise of temperature, but toward close (six weeks after onset) temperature became subnormal; no difficulties of respiration nor cardiac irregularities noted. Died seven weeks after beginning of the attack.

X.—Colored woman, aged thirty-six, imbecile; previous health good. Had an attack of "continued fever" (which was probably tubercular) lasting five weeks. Recovered and was up and able to move about for a week; then developed a violent neuralgic (?) pain in chest, and in a day or two exhibited typical symptoms of neuritis in lower extremities, and a few days later in nerves of arms and body (intercostals) also. Temperature became subnormal. She grew weaker, experienced great difficulty in respiration, and died of asphyxia, without cardiac irregularities, three weeks after disease first appeared. Autopsy showed general miliary tuberculosis, involving pia mater, as well as all internal organs.

XI.—White man, aged thirty-four. Epileptic convulsions for five years past; mental weakness noticed during four years. Health good; muscular and well-nourished. With fever and the frequently noted gastro-intestinal disturbance, the pains, sensory abnormalities, and muscular paresis characteristic of neuritis developed in the arms first, slowly thereafter in the legs, rendering patient nearly helpless. Wrist- and foot-drop marked. The pain was severe from "top of head to sole of foot," as he said; hyperesthesia and absence of reflexes also noted; some edema; later, some muscular atrophy. After four weeks he began suffering from dyspnea and cardiac irregularities, temperature became subnormal, and he died two months after the onset of the disease, of cardiac failure and asphyxia (involvement of pneumogastric, probably).

XII.—White woman, aged forty, utterly demented for many years. Previous health good. The nurse noticed that she seemed indisposed to move from place to place, and that when necessary to move she would get down on the floor and crawl like an infant. Examination showed absence of patella reflexes, inability to stand or walk steadily, sensory perversions, edema, incoördination of movement. Patient was too demented to complain of pain if she experienced any. She showed no constitutional disorder, and refused to remain in bed. She regained the use of her legs after two months. Reflexes were absent after five months, and some atrophy is still apparent, although she walks fairly well.

XIII.—White woman, aged fifty-six. Chronic mania, with great excitement and turbulence. Nephritic, emaciated, and in feeble health, with frequent diarrhea, progressive emaciation, and exhaustion from excitement. After being excited for two weeks she became helpless, and upon examination the usual evidences of neuritis were discovered in the lower extremities—muscular weakness, absence of reflexes, pain and tenderness, inability to stand. Trophic disorders were more prominent than in the other cases—edema and a herpetic eruption, and later a crop of small boils. The neuritis was confined to the legs. Patient died of exhaustion and nephritis about two weeks after disease developed.

It will be noted that the neuritis affected the lower extremities in every one of the thirteen cases, and the lower extremities alone in ten of the cases. The other three cases, in which the nerves of the arms and body became involved, all proved fatal although only one of these fatal results could be attributed directly to the neuritis (Case XI). One of the other cases died of miliary tuberculosis, the third of auto-infection, although death in each case was doubtless hastened by the neuritis. In one case the neuritis developed in course of a miliary tuberculosis, in one it followed a "bilious attack," in one the "Flechsig opium treatment" for epilepsy, in one a doubtful malarial infection; in none of the other cases could a reasonable guess at a cause be made.

The patients were young or middle-aged, and had been insane and in the institution some time; four were epileptic; all were demented more or less; none had used alcohol, and in only one case was a (doubtful) history of syphilis obtained. In most of the cases there was some evidence of an acute general toxemia, usually noted a day or two before the local symptoms attracted attention. In at least three cases, however, symptoms of general disease were lacking. No marked effect upon mental state nor upon the course of the insanity was noted in any instance. An examination of the urine of about three-fourths of the cases was made after the acute stage was passed, without discovering any indication of increased renal irritation, the urinalyses, as a whole, giving the same result as had been obtained at examinations made before the neuritis developed.

Why, after so many years of immunity, we should have a dozen cases of peripheral neuritis within a few months, is not clear, unless we assume the existence of some endemic cause, absent from our locality up to last year, such as is supposed to be active in beriberi—some germ or other

source of infection. Excess of starchy food has been assigned as a cause of endemic neuritis, but here the food of the patients does not show an excess of carbohydrates, and the quality and kind of food has been practically the same for years. Infection also is not clear. While four of the cases occurred in one ward, they all developed about the same time, and no other cases appeared; the remaining nine cases were widely scattered. The summer and autumn of 1895 was, it is known, a sickly season, malarial diseases, among others, abounding. While our neuritis cases, with one exception, obviously did not follow malarial infection, the causes favoring the growth of the malarial germ in the South may have also been favorable to the development of the etiological basis of endemic multiple neuritis. The blood of several of the neuritis patients was examined for the malarial plasmodium, without success. Although cases of multiple neuritis among the general population of the State have not come to my notice, I am informed by Dr. P. T. Vaughan, assistant physician at the Arkansas State Asylum for the insane, at Little Rock, that a number of cases of multiple neuritis occurred among the insane patients at Little Rock about the same time we were experiencing the epidemic at Tuscaloosa, indicating that the cause, whatever it might be, was widely diffused, rather than local or peculiar to the Alabama State Hospital. Several of our cases showed the auto-infection symptoms—dryness of tongue, offensive breath, emaciation, etc., seen in the dry or atrophic form of kakke or beriberi.

A fairly representative composite clinical picture of the disease, drawn from the cases we have seen, is the following:

After a period of malaise, lasting from a few hours to several days, with the discomfort common in the prodromal stages of acute disease, sometimes with a distinct chill, usually with a rise of temperature, together with anorexia, dryness of mouth and throat, furred tongue, offensive breath and constipation, the patient begins complaining of pain in the affected part, the legs most often. The pain is often quite severe, is darting and shooting, or burning, boring, aching, stinging, or "like ants biting," as one patient expressed it. Muscular weakness and incoördination is then noticed, and other sensory disorders appear, as diffuse or irregularly distributed areas of hyperesthesia or (rarer) anesthesia; tenderness on pressure is common, sensations as of "bugs crawling on the legs," "as if the limbs were asleep," are also mentioned. The tendon or deep reflexes are also abolished (noted in all of our cases). The muscular weakness increases in severity, the gait becomes ataxic, patient is unable to get up and down steps, unable to stand steady with eyes closed; the weakness may become only a paresis, but in many cases there is almost complete paralysis at the height of the attack, with the characteristic wrist-drop or foot-drop. The sensory disturbances subside after a longer or shorter time, the motor weakness is more persistent. Trophic derangements, appearing at a later stage than do the sensory and motor disturbances, are also frequent, as edema, eruptions, sores, discoloration, etc., of the skin, or, more rarely, a herpetic eruption, or even a typical herpes zoster. When the motor paralysis becomes well-marked, there is always atrophy of the muscles supplied by the affected nerves, this becoming, in some instances, very marked. Contractures may result. There are then also changes in electrical reaction, either a diminution in galvanic, as well as faradic excitability, or a partial or complete reaction of degeneration.

The disease progresses in intensity for a period ranging from a few days to some weeks, then remains stationary for a shorter or longer time, then slowly disappears, pain first, motor weakness next, reflexes last returning. There are all grades of severity and duration, from a mild paresis, disappearing in a few weeks (Case VI) to paralysis of some months' duration (Case I), or the disease may cause death, as in Case XI. Usually the peripheral extremities only of the nerves are affected, the disease extending to the middle of the arm or to the middle of the thigh, as a rule. In the severer cases, and possibly in a few of the milder grade, the inflammation extends quite to the cord. While the great majority of cases recover, the disease often proves a serious one, as is shown by our three fatal cases among thirteen. Death, when directly owing to the neuritis, as in Case XI, is generally due to participation of the pneumogastric and other respiratory nerves in the disease, death occurring from asphyxia or from failure of the heart.

The diagnosis of peripheral neuritis, save in the cases pursuing an atypic or unusual course, is not a matter of difficulty, the rapidly developing motor weakness, incoördination, loss of tendon-reflexes, together with the pain, perversions of sensation, and trophic phenomena offering a characteristic clinical picture. Very mild cases might be overlooked, the slight pain and muscular weakness not attracting sufficient attention to suggest an examination of the affected limbs, or being attributed to "neuralgia" or "muscular rheuma-

tism," etc. In the severer cases also, the local manifestations may be overshadowed by the marked constitutional disturbance—fever, general prostration and weakness, auto-infection symptoms, etc., but in this, as in the first instance, if an examination of the nerve-reactions is made, there will be little opportunity for error.

The symptoms of poliomyelitis anterior, or infantile spinal paralysis, resemble somewhat those of multiple neuritis. Poliomyelitis, however, is preëminently a disease of infancy and early childhood, and is usually a purely motor paralysis, lacking the sensory disorders of neuritis.

Acute ascending or Landry's paralysis resembles a polyneuritis in many particulars; in fact, many of the symptoms of Landry's paralysis are due to involvement of the peripheral nerves, and some of the reported cases of Landry's paralysis are most probably cases of multiple neuritis; in fact, some (Ross) have insisted upon the identity of the two diseases. The chief differences noted in typical cases are: Landry's paralysis is usually a motor one, the pain, trophic disorders, etc., of neuritis being absent; it advances more rapidly than neuritis, the muscles do not atrophy, and the reaction of degeneration is not present.

When a polyneuritis involves the lower limbs alone, and is of slow onset and progress, as is often seen in cases due to alcohol or syphilis, the disease bears a close resemblance to tabes dorsalis or locomotor ataxia, and well deserves the name of pseudo-tabes, which has been applied to it. The symptoms common to the two diseases are: The pains in the legs, the sensory perversions, muscular incoördination, ataxic gait, swaying with closed eyes, absence of tendon-reflexes. The differences are: The girdle-pain of tabes is not present in neuritis; the lancinating, stabbing pains of tabes are not common in neuritis; the pain in the last-named being continuous, burning, stinging; the pupillary-light reflex, absent in tabes, is not changed in neuritis. There is loss of coördinating power in both diseases, but in tabes there is, at least in early stages, no muscular weakness, while this weakness is marked in neuritis; the "crises" of tabes are absent in neuritis. Thus, in typical cases the differences are sufficiently prominent. In some atypic instances, however, it becomes a matter of no small difficulty to decide between a neuritic pseudo-tabes and a true tabes—a fact not surprising when the pathology of the two is borne in mind. The nerves are usually affected in tabes, and many of the symptoms of tabes are obviously those of the accompanying neuritis; in fact, it has been claimed that locomotor ataxia is a primary affection of the peripheral sensory neuron.

The treatment of multiple neuritis is, first and most important, removal of the cause, if such is discoverable and removable—withdrawal of the alcohol, opium, arsenic, lead, etc., treatment of the syphilitic, malarial, or other infection.

For the neuritis itself, there is no specific. Of drugs, quinin and the salicylates are most often recommended. For the relief of the pain, the most distressing single symptom, coal-tar derivatives or, preferably, opium, may be given. The steady galvanic current is sometimes of service; hot applications give much relief in some cases—hot water, hot flannels, hot poultices. After the acute stage is passed, the aim is to minimize the muscular atrophy and prevent contractures, and to restore muscular power as soon as possible. This is best done by the systematic use of electricity (faradic current) and massage. In the large majority of cases recovery is complete, although from several months to a year, or even longer, may be needed

STERILITY IN WOMEN.[1]

By G. BETTON MASSEY, M.D.,
of Philadelphia.

Aside from congenital deficiencies and anomalies of development of the essential organs of generation, we have been taught, since the days of Marion Sims, that the chief reason for sterility attributable to the woman is narrowness or flexion of the uterine canal. When it is remembered that the narrowest pin-hole os, on careful manipulation, will admit a sound, which is many times larger than the self-propelling spermatozoid, it would seem that this reasoning is inconclusive. It is doubtless to the operative furor that the popularity of the stenosis and atresia theory of sterility is due, for since the days of Sims and J. Y. Simpson, practically no form of treatment has been employed except some method of enlargement of the canal. This was at first accomplished by slitting the cervix. Owing to the combined ineffectiveness, morbidity, and mortality, of this procedure, it has, of late, been superseded by so-called dilatation, which is accomplished only by tearing apart the muscular and fibrous tissues that encircle the canal. Only exceptionally has this accomplished a cure of the sterility, while it is at times followed by serious consequences in the shape of parametritis and diseased appendages. One case of ectopic pregnancy, and a number of instances of uterine and

[1] Read before the Philadelphia Obstetrical Society, September 3, 1896.

ovarian tenderness, have been observed by me after dilatation.

Far more important causes of sterility may be found in imperfect participation of the uterus in the sexual orgasm, catarrhal changes in the mucus of the uterus and tubes, and inactive ovaries—the last two being the most important. A lessened aspiratory action of the uterus, while rendering conception less certain, cannot be a serious impediment on account of the automobile powers of the spermatozoids. This defect may, however, be materially lessened by the general intrapelvic action of electricity, promoting the nerve-tone of the organs, particularly of the uterus and ovaries, increasing muscular activity, and quickening circulation. The method best adapted to accomplish this purpose is the vagino-abdominal galvanic application with covered vaginal electrode, which should be negative, a current of from thirty to forty milliamperes being turned on and off gradually and repeatedly by the swelling method. This may be supplemented with labile lumbar applications of the galvanic current to the sexual center of the cord, the patient lying upon the face with a large pad under the abdomen.

Of the toxic effect of altered uterine secretions on the fertilizing cells of the semen there can be no question, and it is in these cases that galvanic electricity, applied within the cavity of the uterus, is of the greatest service by its alterative action on the secreting surface. Unless the intrauterine treatment is indicated also by marked changes in the mucous membrane, the covered elastic electrode is best as promoting favorable changes in the mucous membrane with least traumatism. It has been my habit to employ the positive pole usually, though the choice of pole for this purpose is open to further investigation to determine whether the normal alkalinity of the uterine mucus should be increased by the negative pole or diminished by the positive pole. Possibly the results depend rather on the simple excitation of a more normal secretion.

Deficient activity of the ovaries can only be inferred as a cause of sterility, in the absence of any demonstrable lesion or more patent defect of functionation on the part of the woman, and, of course, after the question of the possible sterility of the husband has been eliminated. It may or may not be associated with lack of sexual appetence and responsiveness, for many women conceive readily in whom the orgasm is deficient or absent. Any method of treatment that promotes increased activity of the pelvic circulation, such as negative vagino-abdominal applications of either current, may increase ovulation, while the musculo-tonic effect of the galvanic current, by the swelling method, may do much to lessen a practical maternal impotence from weakened musculation, which is only less disastrous to the conjugal relation than similar conditions of the male.

But few instances of this affection have been placed under my care for the purpose of curing the sterility—but five in all—in four of which the treatment outlined was successful at some time during a year following the cessation of the treatment, two instances being almost immediate. In the one case that was a failure up to the date of her last report to me, the ovaries were both prolapsed and the tubes also probably involved in the remnants of an old pelvic inflammation. Her symptomatic condition was nevertheless improved.

The slight attention paid to this subject is doubtless due in part to a lack of information as to the value of this method in certain cases, and, in part, to a prevalent disinclination of American women for the burdens of maternity. That electricity may cure sterility, when the patient only seeks relief from the pain of chronic metritis, is abundantly shown by a tabulated report made by the writer to the American Electro-therapeutic Association in 1894,[1] where, of thirty-two cases of uterine disease that involved, in each instance, at least a temporary or acquired sterility, eight had become pregnant after the treatment. Apostoli, at the same meeting, reported pregnancy in eighty cases after intrauterine electric treatment, some after one application. Of the twenty-two cases reported *in extenso* in the paper,[2] five were nulliparæ.

An interesting case of this sort was sent to me in August, 1892, by Dr. Whitcomb of Greenwich, N. Y. She was a lady, twenty-nine years of age, who had been married five years without the least sign of pregnancy, but who came to me for a hemorrhagic menorrhalgia, which she had suffered from both before and since marriage. The only perceptibly abnormal conditions were a slight leucorrhea, and an enlarged corpus uteri, the cavity being three inches in depth. Under positive intrauterine applications she improved rapidly, the applications finally being made but once a month. About this time I was surprised by what appeared to be a very painful period, accompanied by clots, and counseled a waiting policy for some months to determine what her condition would be without treatment. At her next visit, some two and a half months later, she stated that the following period had been painless and normal, but that she had seen nothing since then. An

[1] "Trans. Amer. Electro-therapeutic Assoc.," 1894, p. 78.
[2] "Trans. Amer. Electro-ther. Assoc.," 1894, p. 371.

examination gave rise to a strong presumption of pregnancy, then existing, and convinced me that the painful period of some months back had been a miscarriage inadvertently brought on by the treatment preceding it. She was sent home this time without treatment, and in due time gave birth to an unexpected but much-desired daughter.

URETHRAL AND VESICAL ARTHRITIS.[1]

By A. H. LEVINGS, M.D.,
of Milwaukee, Wis.

Urethral arthritis, more often, but incorrectly termed gonorrheal rheumatism, is of not infrequent occurrence, usually making its appearance during the decline of gonorrhea, or during the continuance of a gleety discharge. The inflammation may be confined to the synovial membrane, and be attended with pronounced effusion. It is more usual for a distinct arthritis to occur, synovial membrane, subsynovial connective tissue, capsule, and ligaments, being involved. Should suppuration within the joint occur, the cartilages and bones may be involved and destroyed. Inflammation of, and effusion into, the tendon-sheaths are also of frequent occurrence, and are of importance as diagnostic symptoms. Urethral arthritis occurs during the later stages of a gonorrhea, or during gleet, on account of the inflammatory destruction of the mucous membrane, or its epithelial lining, which produces the gonorrheal ulcers in the posterior urethra, and affords ready access for the germs or their ptomains to the lymphatic or venous circulation.

Some bacteriologists claim that the gonococci are the direct cause of urethral arthritis; that these germs gain an entrance to the lymphatics or venous circulation through ulceration in the urethra, and are carried to the joint, where they set up their characteristic inflammation. Others hold that the process is one of mixed infection, the gonococci, by destroying the epithelial lining of the urethra, simply preparing the way for absorption of the pyogenic or pathogenic germs, which are known to inhabit the urethra under normal conditions, or which may be introduced mechanically. If the inflammation is confined to the synovial membrane, and the exudate is serous in character, statistics show that in thirty-five per cent. of the cases, recovery takes place with complete restoration of the functions of the joint. If the inflammation attacks all the structures of the joint, and the exudate is sero-fibrinous, sixty-five per cent. will be attended with restriction or complete loss of motion. If the exudate is purulent, more or less destruction of the joint is almost certain to follow, the condition probably necessitating resection.

In seven cases, which have recently come under my care, in two the hip was implicated, one the knee, one the knee and shoulder, one the metatarsal, one the metacarpal, and one the ankle-joint, and in 299 cases tabulated, the duration of the articular inflammation averaged sixty-eight days. Gonorrheal rheumatism is put down by Gresolle at $2\frac{4}{5}$ per cent. of all cases of gonorrhea.

Urethral arthritis is a typical infective arthritis, and in its symptoms and course is to be differentiated, especially from acute rheumatism for which it is often mistaken. Its chief characteristics are that it attacks but one, or at most, but few joints, those of the knee, shoulder, ankle, or the metacarpo- or metatarso-phalanges, being most frequently affected. It has a less abrupt onset than acute rheumatism, but far greater persistence. The pain attending it is often more severe than in the most aggravated case of rheumatism. The inflammation implicates most frequently all the structures of the joint, instead of being confined to the synovial membrane, as is the case in acute rheumatism. Inflammation of and effusion into the overlying tendon-sheaths are also prominent characteristics, and may continue for weeks, or months, or perhaps years, uninfluenced to any great extent by internal medication, and followed, in prolonged cases, by decided anchylosis, due to the organization of the fibrinous exudate binding the various structures of the joint together. Suppuration is uncommon, occurring only twice in ninety cases tabulated by Nolan. Osler relates a case where the patient was practically bedridden for ten years from gonorrheal rheumatism.

The following cases, which recently came under my observation, may be of interest:

Case I.—S. J., aged twenty-nine, confessedly having had gonorrhea, followed by a gleety discharge and cystitis, was attacked, August 30th, with sickness at stomach and dizziness; the second day following, all of the metatarso-phalangeal joints of the left foot became involved. After three days the corresponding joints of the right foot were also attacked. I saw the patient for the first time September 16th. At this time he was suffering excruciating pain, being wholly unable to sleep, even from the effects of large doses of opium. He had been treated with the salicylates without effect. His temperature ranged from 101 to 103° F. The greatest pain was in the metatarso-phalangeal joint of the great toe of his left foot, and in the tendon-sheath of the second toe of the right foot. The whole metatarsal region of the right foot was much swollen from implication of the tendon-sheaths. After some

[1] Read at the Fox River Valley Medical Society, June 21, 1896.

days of treatment, no improvement taking place, and fluctuation being pronounced, I cut down upon the tendon of the second toe and joint of great toe. A very considerable quantity of pus was discharged in each instance. Following this the right foot quickly recovered, but no improvement taking place in the left, the joint was resected, the bones being in an advanced state of caries. The patient made a quick recovery, and, excepting some disability, is at the present time quite well. The case is of interest on account of suppuration having taken place in the tendon-sheath of one foot, and in the joint of the other.

Case II.—Mr. H., aged thirty-one, contracted a gonorrhea in August last. He consulted me in October on account of inflammation in his right ankle-joint, pain over both ossa calci, and in the muscles of his back. The pain in the heels was so severe, and the deep structures so sensitive, that he could only walk on the balls of his feet. The muscles of his back and neck were sensitive and in a state of tension. I then learned of his previous gonorrhea. The urethral discharge had, however, ceased, but there was increased frequency of urination which was slightly painful. Having the patient pass his urine into two glasses, the second glass was seen to contain the characteristic pus-threads and flocculi of a posterior urethritis. The passage of a sound showed the posterior urethra to be inflamed. The patient was given salol internally, and was treated locally by the passage of a sound every second day, followed by a deep urethral injection. I instituted this local treatment with the expectation of curing his post-urethral gonorrhea, and thus indirectly relieving his joint, periosteal, and muscular inflammations. But I was disappointed, for with each passage of the sound and the use of the injection, his condition was made worse. The pain in the heels, in the muscles, and the inflammation in the joint grew worse, until finally he was forced to take to his bed, whereas, when he came to me he was able to be out of the house a little with the aid of two canes. The local treatment was then discontinued, while internally the salol was continued with tonics. He was also directed to drink copiously of water. Under this treatment he has now practically recovered.

Case III.—Mr. J., aged thirty-five, had had numerous attacks of gonorrhea, and was suffering during the winter of 1894–5 from stricture, with a gleety discharge. He had been under the care of various surgeons for the cure of his ailments without receiving any permanent benefit. One day his doctor either forced a large sound through the stricture or created a false passage. The pain caused thereby was excruciating, and, when he was driven home, he fell upon the floor in a faint, his clothes saturated with blood from the urethra.

The next day he developed a violent arthritis of the right knee. I saw the patient in consultation some ten days after the joint had become inflamed. He was then much emaciated, had a high fever, and was suffering intolerable pain in the knee. He had a urethral discharge, and the urine was loaded with pus. The condition of the joint was typical of gonorrheal arthritis, all the structures being acutely inflamed, including the incrusting cartilages, as shown by the starting pains and spasmodic muscular contractions, occurring at night or on the slightest motion. There was also considerable effusion within the synovial sac. This was aspirated, the joint enveloped in a thick layer of absorbent cotton, surrounded by a firm bandage and immobilized in a plaster cast. Extension was applied from below the knee. Internally salol, potash, and balsam, were given. No local treatment was attempted. In ten weeks the patient had so far recovered as to be down-town with the aid of a crutch.

The remedies which are so efficacious in acute rheumatism have little if any effect in urethral arthritis. To remove the cause, to cure the gonorrhea, thereby preventing further systemic infection, would seem to be the most rational method of treatment. The local treatment by sounds and injections is usually contraindicated, unless there be pronounced stricture, as their use causes abrasion and favors absorption. Something may, however, be accomplished with remedies which exert an antiseptic effect upon the urine, as salol, boracic and benzoic acids, and quinin, and with those which increase the quantity and lessen the activity of the urine, as well as with those which exert a favorable specific influence through the urine on the inflamed urethral mucous membrane.

In the primary local treatment of the arthritis, compression by bandage over a layer of absorbent cotton, with rest, secured by immobilization, and extension, if the disease is at the knee or hip and has attacked the incrusting cartilages, are the most important indications to be met. Should the effusion be excessive and serious, aspiration may be practised. If pus-formation has taken place, incision with drainage, or excision will be necessary. As there is great liability to partial or complete ankylosis, absolute immobilization should not be continued after the acute symptoms have subsided. For the purpose of hastening the absorption of the sero-fibrinous exudate and favoring the restoration of the joint functions, after the subsidence of the inflammation, passive motion, massage, and electricity, are useful. The repeated production of small blisters over the joint, or the frequent application of the Paquelin cautery, has given me excellent results.

Non-gonorrheal vesical arthritis, though not as

frequent an affection as gonorrheal urethral arthritis, occurs, nevertheless, sufficiently often to render its diagnosis and treatment important. It is met with most frequently in old men, who, either in consequence of an enlarged prostate, or atony of the muscular fibers of the bladder, have that train of symptoms which are the result of an incompetent bladder, residual urine, infection, decomposition, cystitis. The pyogenic microorganisms or their ptomains in the bladder gain an entrance to the venous or lymphatic circulation, find a lodgment in a joint or joints, and there set up inflammatory action. Clinical experience seems to teach that a chronic rheumatic arthritis acts as a predisposing cause to vesical arthritis by creating a *locus minoris resistentiæ*. The following is the history of a case now under my care:

An old gentleman past seventy, with enlarged prostate and incompetent bladder, had been suffering, more or less for several years, with a gradually increasing cystitis. When I first saw him, more than two years ago, he had been confined to his bed for four weeks. This confinement was not wholly nor largely on account of his cystitis, which was nevertheless severe, but on account of inflammation of the joints of his legs, knees, ankles, and feet. Not more than one or two joints were usually acutely inflamed at any one time. When the patient came under my care his limbs were encased in flannels, and it was with the greatest difficulty that he could be moved in bed. Believing that I had before me an infective arthritis, the result of the suppurative inflammation in the bladder, I directed all my attention and all my treatment to the latter organ, and as the condition of the bladder improved, the inflammation of the joints subsided. At the end of the second week of treatment, the pain, swelling, and soreness, had almost entirely left his joints and he could move them quite freely. At this time there occurred a slight exacerbation of the cystitis, and immediately the left ankle became swollen, red, and painful, which subsided again as the bladder improved, and during the fifth week of treatment he was out of bed and walking fairly well, when there occurred a second exacerbation of the cystitis, caused by a too strong injection of nitrate of silver. Almost immediately the right knee became acutely inflamed, the inflammation subsiding with improvement of the cystitis. During the two years and more that this patient has been under my care, he has been confined to his bed five times for short periods on account of acute inflammation of some of his joints, the joint inflammation being always coincident with an increase of his cystitis from neglect of local treatment, and the instituting of local treatment has in each instance been followed by a rapid disappearance of the joint inflammation. I have seen many cases similar to this during the past two or three years, though this one is perhaps the most typical.

In the treatment of this class of cases it is of great importance to restore, as far as possible, the functional power of the bladder by the administration of strychnin and tonics, to lessen the decomposition of the urine by the use of salol and quinin, and to relieve the cystitis by washing out the bladder. Probably no medicinal substance is so often used for the latter purpose, and, in my experience, is of so little value as boracic acid. Combined with carbolic acid it is of unquestionable value. Borax is also a favorite remedy with some. In cases where the urine swarms with bacteria, very great benefit is derived from washing the bladder with the bichlorid of mercury solution 1–12,000, or 1–15,000, or permanganate of potassium grs. 5 to 15 to the quart of water, although the former is often followed by severe pain. An occasional instillation into the bladder of from one-half to one dram silver-nitrate solution, of the strength of from one to three per cent., is of value. In my own practice no one remedy has perhaps given me greater satisfaction than the non-alcoholic fl. ext. of goldenseal, one dram to the quart of water. It is my practice to wash the bladder with this solution for two or three days, always leaving a syringeful in the bladder after the washing; then for an equal number of days to wash with the carbolic and boracic acid solution, and about once a week to instil a dram of the solution of nitrate of silver into the bladder after thoroughly washing it out with boiled water, and occasionally, if the microscope shows the microörganisms to be in large numbers, washing the bladder with the bichlorid of mercury or permanganate of potassium solutions. I believe a large number of patients, if patiently and perseveringly treated in this manner, may be saved, at least for a considerable time, the serious operation of castration or drainage.

Note.—Since the writing of this article, two additional cases have come under my care, one of gonorrheal arthritis, where the left hip and right knee were inflamed, the other a case of vesical arthritis, occurred in an old gentleman, aged seventy-six, with enlarged prostate, cystitis, and residual urine loaded with pus. In this case three distinct attacks of arthritis have occurred during the past three months, each being coincident with an exacerbation of the cystitis. Evidence of the direct causal relation is constantly accumulating.

CRANIOTOMY ON THE DEAD CHILD.[1]

By JOS. B. De LEE, M.D.,
of Chicago, Ill.;
Lecturer on Obstetrics, Northwestern University Medical School; Obstetrician to Mercy Hospital and Chicago Lying-in Hospital Dispensary.

This subject is one of great importance, and it is one that is seldom, if at all, found in our literature. We read many articles in the journals on "Craniotomy on the Living Child," "Is it Justifiable?" etc., etc. It is the intention of this paper to leave this subject entirely alone.

Of all obstetric operations, the most common is the forceps. Not infrequently, the operator finds that in spite of very strenuous efforts, he can make no effect on the progress of the child. This is usually due to a mistake in the diagnosis of the position of the head, or to the failure to recognize the existence of a contracted pelvis. At any rate, the attempts at delivery are continued, another physician helps pull, and together they succeed in delivering a dead child, or one so crushed that it dies in a few hours. As for the mother—she has severe cervical, vaginal, and vulvar tears, has *post-partum* hemorrhage, sepsis in the puerperium, happily comes through with her life, but carries the effects of such brutality in the shape of severe cellulitic thickenings in the parametria, adherent uterus, probably life-long invalidism. I have known a physician to pull four hours on the forceps, knowing all the time that the fetus was dead.

The second operation that is too often undertaken to get around the necessity of hurting the dead child, is version. In cases of contracted pelvis, where, in spite of strong pains, the head has not passed the inlet, if the child is dead, craniotomy is the proper operation. I exclude here cases of absolute contraction, referring to those where the conjugata vera is from 3 to 3½ inches. To do a version here is foolhardy. (1) The operation of version is one that, except in the most favorable cases, requires considerable skill in technic; (2) it has always the attendant danger of rupture of the uterus, especially in cases where the lower uterine segment has become thinned during the ineffectual attempts of the uterus to force the head past the obstruction.

The operation of craniotomy is simple, requires less skill than a version, has no attendant dangers, other than those which the operator can avoid, sepsis and injury to the soft parts.

Embryotomy and not version should be chosen in neglected transverse or shoulder presentation. In cases of transverse presentation where one is called early, the child being alive, version is the proper operation. Even when the child is dead, if the bag of waters has only recently broken, and the uterus presents none of the symptoms of threatened rupture, a version may be quite easy, and, in comparison with decapitation, may seem the better operation. Again, one might not have the necessary instruments at hand, but where the labor has been neglected, in cases of contracted pelvis, and where an attempted version meets with even moderate resistance, reject the operation and do an embryotomy.

Again, it may happen, that during an extraction by the breech, the head becomes arrested at the inlet. During the long ineffectual attempts at delivery, the child dies. The operation of election here is craniotomy. In the absence of a perforator, use a pair of scissors.

The following cases will serve to show that the conditions I have described do exist:

Case I.—Primipara, aged twenty-two. Labor eighteen hours, face presentation, mento dextra anterior, head not fully engaged, cervix effaced, and os dilated for several hours. Child dead. Forceps, powerful traction, no progress. Council. Counsel advised forceps, doctor in charge, craniotomy. Counsel with feet braced against the bed, two assistants holding the woman by the arms, after the hardest labor, delivered a large dead fetus. Smart hemorrhage, deep perineal tear; during the puerperium the entire vagina sloughed out. Slow recovery; place where vagina should be, filled with connective tissue, leaving an orifice so small that the finger cannot pass. Later plastic operation, in which flaps were made from the skin of the buttocks, the scar tissue dissected out and a vagina two inches long constructed. Result fair.

Case II.—Multipara. Contracted pelvis, breech presentation. Midwife called assistance because the head would not come. One physician pulled on the body till he got tired. A second succeeded in tearing the body off the head, which was retained in the utero. Now there was nothing to catch hold of but the jaw. A third physician succeeded in ripping this out. Still the head would not come! The fourth physician finally, by pushing his fingers into the orbits, was able to deliver the rest of the head.[1] The poor woman died in three hours.

Case III.—Primipara, normal pelvis, large child. Head movable above the inlet. Forceps, long and powerful efforts, but no progress. Child died during these tractions. An attempt at version succeeded only in bringing down a foot alongside the head. Operator, now exhausted, gave place to another who, with great force,

[1] Read before the Illinois State Medical Society, May, 1896.

[1] Cocq says forceps, in generally contracted pelvis, is equivalent to embryotomy.

completed the version. In the extraction which followed, the perineum was torn through the anus, a tear extending four inches up the recto-vaginal septum. Primary suture sloughed, now permanent incontinence of feces. Craniotomy was not done because it was thought too dangerous. And these operations were not dangerous!

Case IV.—Reported in the New York Obstetrical Society last year. Occipito-posterior position, head still movable. Placenta prævia marginalis. Prolapse of the arm and the cord. Truly a complicated case, but the *child was dead.* The following operations were done to deliver the lifeless foreign body: (1) Forceps used to try to correct the bad position of the head. (2) Forceps as an instrument of extraction using all possible power, and kept up for a long time. (3) Incisions in the cervix. (4) Forceps again after this. Failure. (5) Version, during which the back turned to the mother's back, making the bringing down of the arms very hard. (6) Forceps on the aftercoming head! The woman died in forty hours.

It is encouraging to note that the paper was very sharply criticized, and the proper treatment advanced, at the time it was read. If the child had lived at the time of the first examination, the proper operation was version. This was indicated by all the conditions, placenta prævia, posterior occiput, prolapse of the hand and cord. But the child being dead, the cervix only large enough to admit the forceps, and in the presence of an indication for the termination of labor, there was only one operation to do—craniotomy. Can there be any doubt that, if this operation had been performed, the woman would have lived? It is easier and less harmful that any single one of the methods employed to deliver this case.

The late Dr. W. W. Jaggard said, "the necessary mortality of craniotomy is zero." Winckel says, "the percentage of maternal deaths in the hands of skilful operators is reckoned at 0 after perforation, and as at least 8.4 per cent. after the Cæsarean section. The former is entirely free from danger, and the latter can be designated as quite dangerous, etc."

In cases where labor has become so complicated that the operation is imperatively demanded, especially where violent attempts at delivery have been made, a certain number of deaths must occur, but these cannot be laid at the door of craniotomy. For this reason all statistics regarding the operation are valueless, unless the foregoing operations have been considered, *i.e.*, whether the craniotomy has been undertaken as a primary operation, or only as a last resource. In seventy-one cases by Leopold of Dresden, two deaths occurred, and both from eclampsia, for which the operation was undertaken. This leaves the mortality of the operation itself at zero. Fehling in twenty-three cases, lost one woman from eclampsia. These statistics are taken from the present antiseptic and aseptic era, and from good operators, being the only reliable figures that could be found. Busey of Washington, in an eloquent plea for the abolishment of craniotomy on the living child, gives many different statistics. According to the totals, the mortality varies from seven to twelve per cent. This includes cases where Cæsarean section should have been done for the absolute indication, and all cases where ineffectual attempts at delivery had preceded the craniotomy—the last hope.

Why should there be any mortality from craniotomy if it is properly carried out? The operation can always be done slowly, there is plenty of time to prepare everything according to the most stringent rules of asepsis. The perforation of the head under the guidance of the fingers is done with absolutely no injury to the mother, and the subsequent application of the cranioclast is simpler and easier even than the forceps. Care is required in the extraction of the child to protect the soft parts from splinters of bone. If the cervix is not dilated, gentle traction, repeated often, dilates it evenly and safely. Absolute cleanliness protects the patient from infection.

In the last year alone, I have had occasion to do two craniotomies, both for contracted pelvis, and both in the hovels of poor people. Recovery in both cases was prompt. A perforator and a cranioclast are the instruments needed. The latter is simply a large and powerful bone-forceps. While the instruments are boiling, the field of operation is sterilized.

The cervix needs to be large enough to admit three fingers, but the larger it is the better, and in the absence of contraindication, one may wait for sufficient dilatation. The four fingers of one hand are then passed into the vagina and come to rest on the head. The perforator is passed under the cover of these fingers, and does not touch the maternal tissues at all. The head being steadied from the outside, with a gentle boring motion, the point goes easily through the head. The handles are next unlocked, and the blades opened to their full extent. The instrument is locked, turned one quarter of a circle, and reopened. The handles are again locked, and the perforator is carefully withdrawn.

Brain matter flows out, and if the pains be strong, they may force the head into the pelvis.

It is not advisable to leave the case to nature, rather extract. With the same precautions as in forceps, the blades of the cranioclast are passed, the solid one inside the opening which was made, the other one over the face. They are locked and screwed together. The head is extracted as if it were in the grasp of the forceps, using the same rules to pull with a pain and to pull in the axis of the pelvis. After the labor, a thorough vaginal douche or an intrauterine antiseptic douche is given.

In conclusion, I wish to give the following indications for craniotomy: (1) All cases where, the child being dead, an indication for the termination of labor arises. This operation should be done instead of the forceps, when the maternal soft parts are unprepared for rapid delivery. Such cases are eclampsia, placenta prævia, premature detachment of the normally implanted placenta, prolapse of the cord with danger to the mother from any cause—in short, don't apply the forceps on a dead child. The only exception I would make to this rule is the case of a multipara, with the head low down and the soft parts well prepared. (2) Cases of contracted pelvis when the conjugata vera is not smaller than 2½ inches. To do a hard version or extraction, or a forceps, or a Cæsarean section, is not justifiable when the child is dead. (3) In neglected transverse presentation, embryotomy should be done. The thought of a version should not be entertained for a moment.

CLINICAL MEMORANDA.

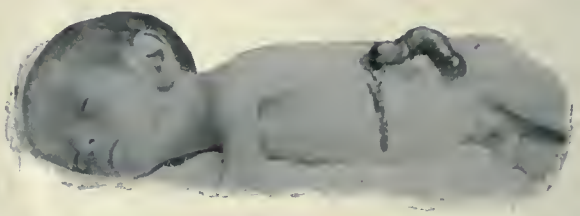
A CASE OF IMPERFORATE ANUS.

By C. D. SPIVAK, M.D.,
OF DENVER, COL.;
ASSISTANT IN MEDICINE AND LECTURER ON DISEASES OF THE STOMACH AND INTESTINES IN THE MEDICAL DEPARTMENT, UNIVERSITY OF DENVER.

THE rare occurrence of congenital malformations of the rectum (1 in 22,218)[1] justifies me in reporting a case which has come under my treatment.

The baby, a boy, on the second day after birth, was noticed to be sick. He passed urine, but the bowels had not acted since birth; there was no discharge of meconium. He vomited the milk curdled, and once also vomited fecal matter. The abdomen was distended, painful on pressure; there was violent straining. The perineum was smooth, the raphe extending from scrotum to coccyx. Not even a dimple marked the anal site. The superficial veins presented the shape of caput medusæ—prominent and tortuous. On deep pressure over abdomen or the descending colon no bulging was noticed at the would-be anal orifice, and no tumor or fluctuation could be detected. The genital organs were to all appearances perfectly developed, the penis being somewhat longer than normal, as can be seen on the accompanying figure. The case was diagnosticated as complete absence of the anus, the rectum being abnormal and ending at a greater or less distance from the normal outlet.

An attempt to reach the rectal pouch through the perineum was decided as a means of relief, and the consent of the parents readily obtained. The child was placed in the lithotomy position; no anesthetic was used. The incision was made in the median line over the raphe from the root of the scrotum clear to the tip of the coccyx. The tissues were divided by a small scalpel, slowly and carefully, using the finger for exploration. The space between the rami of the ischia was so small that the operation, simple as it may seem to have been, was indeed very tedious. I kept pretty close to the anterior surface of the coccyx, and carried my incision about two inches and a half deep near the coccyx and about one inch at the scrotum. The operation was almost bloodless; no vessel had to be tied. The child was perfectly quiet and unconcerned, it having made an outcry only when the first incision was made. No bulging was detected by the exploring needle, and the operation was abandoned.



PROTRUSION OF INTESTINE AFTER COLOTOMY.

On the following day, the third after birth, Professor E. E. Montgomery saw the case in consultation with me. The operation of colotomy was decided upon. Owing to the fact that the descending colon was visible and palpable through the thin abdominal walls, Amussot operation was chosen. A longitudinal incision was made over the gut on a line about one inch below the umbilicus. The edges of the wound were everted and the peritoneum secured by several stitches to the edges of the skin. The gut, which presented itself as soon as the opening was made, was secured to the edge of the wound by several sutures of fine silk, and then slit open. A large quantity of meconium was discharged with a hissing sound of escaping gases. The wound was cleaned by a weak solution of bichlorid of mercury and a pad of borated cotton was applied and lightly bandaged. The abdomen became of normal size; the child fell asleep quickly. It took the breast greedily; vomiting never returned.

The feces, well formed, were discharged through the artificial anus two or three times daily, the parts being kept clean by a boracic-acid wash. The wound healed kindly.

On the fifth day after the operation the proximal and distal ends of the gut began to protrude, and formed a sausage-like body constricted in the middle, which can be seen on the accompanying figure. The feces were dis-

[1] Kidd, Dublin *Journal Medical Science*, 1896, 3s. c., p. 121.

charged from the proximal end. Frequent replacing of the gut and gentle plugging with gauze and bandaging were of no avail. On the tenth day after the operation the everted and protruding ends of the gut attained their maximum length, about six inches, the proximal end being the shorter of the two. On the thirteenth day after the operation diarrhea set in, and the case terminated fatally on the nineteenth day after birth.

The autopsy revealed, to our astonishment the existence of a well-formed anus occluded by integument only and terminating at the scrotum, about a fourth of an inch from the incision, running almost alongside of the urethra, but not communicating with it. The internal organs were normal and in situ, but the vermiform appendix was abnormally long.

The points of interest to be deduced from the case are as follows:

(1) That pressure over the abdomen does not in all cases produce bulging in the perineal region, and therefore its absence does not preclude the existence of the rectum in that region; (2) that a sound should be introduced into the bladder, and kept there while operating, in order to facilitate exploration; (3) that the incision should be made from the coccyx clear to the urethra; (4) that Littré's operation should be preferred, which is made nearer to the natural outlet, and thus the protrusion of the distal gut, at least, could be avoided; and (5) that colotomy is absolutely justifiable.

A CASE OF EXOPHTHALMIC GOITER TREATED BY THYROIDIN.

By R. M. WHITEFOOT, M.D.,
of Bozeman, Mont.

Miss B., aged eighteen, good physique, well developed, good family history, was brought early in August, 1895, to me for treatment. She presented all the well-marked symptoms of goiter, enlargement of the thyroid gland, protrusion of the eye, increased action of the heart, and general atrophy, with profuse menstruation and disturbance of the nervous system. I concluded to try the juice of the thyroid gland, or rather the active principle, in half-grain doses, three times a day, commencing August 14th. The patient seemed to feel the effects of the treatment very quickly; in two weeks there was a marked decrease in the size of the tumor, the eye was less prominent, and the heart action improved, though she became emaciated, low-spirited, and mentally very erratic. From being unusually light-hearted, cheerful, and amiable, she became morose and fretful. Her mother and sisters became alarmed, fearing her mind might become permanently affected; however, the improvement in the diseased gland was so great, and continued improvement so evident, that I persuaded her mother and herself to continue, and at the end of a month the tumor was reduced at least one-half in size, and the eyes were almost natural. The heart did not respond so readily, but I attributed that to some extent to the nervous tension and mental emotion. As she lost her appetite and suffered from nausea, owing, I think, to imagination and dread of being obliged, at regular intervals, of having to take a dose of medicine, I was obliged to suspend the treatment three times, and to reduce the doses to twice a day several times for a day or two, but on the whole the patient was under the effects of the medicine for about sixty days, or till the early part of October, when all signs of the disease had disappeared. Her heart's action became normal, the eyes had assumed a natural appearance, and though her mental condition was not satisfactory, I trusted to time and surroundings to correct that. I am happy to say that my hope has been realized. She gradually returned to a normal condition, and is, at this date, perfectly well, cheerful, bright, plump, and her menstrual functions are regular. Her family history would indicate neurotic origin, her parents both being extremely nervous. Her mother, though of good physique, is hysterical and very excitable, and the father, while of more than ordinary intelligence and with a good physique, is of a morbid, melancholy temperament, and very depressed at times. There are five sisters, no brothers. They are all stout, healthy girls, but of extremely nervous type.

MEDICAL PROGRESS.

Alcoholism in Europe and its Relation to Insanity.—In a paper recently published (*Thèse de la Faculté de Paris*, No. 219) Darin states that alcoholism is increasing in Italy and Belgium, and especially in France, while it is decreasing in Norway, Switzerland, and Germany. Corresponding to this increase, the number of lunatics in France has also increased. The gain has been chiefly in the two types of insanity known as alcoholic mania and general paralysis. This relation between alcoholism and insanity is also shown by the statistics of different portions of the country, for in those districts where alcoholism is most marked insanity is most common.

The hereditary effects of alcohol are not less striking, for, according to Legrain, among 814 children of alcoholic parents were 322 degenerates and 174 who had not sufficient vitality to live. Among the survivors are fourteen per cent. of hysterics and seventeen per cent. of epileptics.

General paresis has increased in Paris in proportion to a greater frequence of alcoholism.

Surgical Treatment of Tuberculous Testicle.—Tillaux gives (*Bull. Méd.*, 1896, p. 533) his conclusions from a wide surgical experience as follows: (1) In suppurative cases with fistulæ, in which epididymis and testicle are almost destroyed, try to prevent the spread of the disease without operation by deep cauterization, drainage, iodoform gauze, etc. Castration may be inevitable. (2) In non-suppurative cases in the adult the treatment should be constitutional and expectant. Recovery often follows. (3) In non-suppurative cases occurring before the twenty-fifth year the affected part is to be removed, but the resection should be confined to the diseased tissue, *e.g.*, the epididymis alone.

Syphilis Contracted from a Razor.—Catrin in *La Presse Méd.*, June 20, 1896, reports the case of a young

man, aged twenty-seven, who contracted syphilis in September, 1894. The initial lesion was followed by a secondary variola and mucous patches. Despite treatment, the improvement was slow.

In July, 1895, the father of this young man, while using his son's razor, cut himself in the chin. This slight wound became an ulcer with indurated border, accompanied by a painful submaxillary adenitis. Well-marked secondary symptoms developed. He was given large doses of the protoiodid, which developed an obstinate stomatitis. In March, 1896, there was a double iritis, which yielded to mixed treatment.

The author insists that this case teaches physicians not to regard too lightly the possibility of contagion in the second stage of syphilis.

Malignant Growth in the Lung, Diagnosed by the Sputum.—In *Virchow's Archiv*, vol. 142, p. 86, is a description of a case of primary carcinoma of the lung, in which the diagnosis was made several weeks before death by means of a microscopical examination of the sputum. The patient, a woman, aged fifty-four, who had suffered for many years with chronic bronchitis, began to expectorate blood in small quantities. As there was a tubercular family history, her attending physician made the diagnosis of phthisis. There was evidence of consolidation in the right lung from the fourth dorsal vertebra downward. There was no fever. The fresh sputum contained blood, fat drops, and granular cells; but its striking characteristic was the presence of large numbers of large, round cells, arranged in bands with one or more nuclei and from one to four nucleoli. On this ground the diagnosis of pulmonary carcinoma was made—a diagnosis which was proven to be correct by the autopsy, two months later. The cells in the sputum, according to the writer, Betschardt, occur in smaller masses in carcinoma than they do in sarcoma of the lung, because of the denser stroma in the former variety of malignant growth.

Mechanical Treatment of Chronic Constipation.—Schreiber (*Wiener med. Presse*, 1895, Nos. 21–22), divides the forms of chronic constipation into four: (1) That which characterizes young individuals who are otherwise strong and hearty; in these cases a hereditary diathesis or a sedentary life may be the etiological factor. (2) The constipation which attends the various disorders of the digestive apparatus. (3) The constipation of the neurasthenic and anemic persons and such as have deteriorated in bodily tone. (4) The constipation of the obese. In all these types the most reliable treatment is the mechanical one, which consists in massage and suitable gymnastics. In the second form the regulation of the diet should assist the mechanical treatment. In the third form, a change of surroundings, recreation, and hydrotherapy may give good results in connection with the mechanical method. In chronic constipation purgatives and clysters do more harm than good.

An Aseptic Operation for Gangrenous Strangulated Hernia.—In the *Centralblatt für Chirurgie*, No. 33, 1896, Bogdanik describes a method of treatment of strangulated hernia by which he believes the danger of infection is reduced to a minimum. Peritonitis arising after operation for a gangrenous strangulated hernia is due, according to the author to infection at the time of operation. To avoid this he hit upon the plan of removing with scissors and knife all the gangrenous tissue of the sac and its vicinity and disinfecting the wound with carbolic acid solution. The gangrenous intestine is then washed with carbolic solution and dried with sterile gauze, clamped and wrapped in gauze. The ring is divided sufficiently to permit the drawing forward of several inches of normal gut and resection and circular enterostomy are performed. Another washing and sponging takes place, and the loop of intestine is replaced in the abdominal cavity.

The Best Way to Open the Bladder Suprapubically.—Dandolo (*Centralblatt f. Chirurgie*, No. 33, 1896) performs suprapubic cystotomy as follows: After the properly distended bladder is exposed it is seized and divided longitudinally through the muscular layers only. Then two silk stitches are passed through each edge of the muscular wall, and the mucous membrane is divided between them. By this method any blood-vessel which needs tying is easily exposed, the division of the mucous membrane is performed under the eye and not blindly, and the mucous membrane is not necessarily included in the suture.

THERAPEUTIC NOTES.

The Local Treatment of Ocular Diphtheria.—Hertel describes the plan pursued in the treatment of ocular diphtheria at the Ophthalmic Clinic of the University of Jena. General and local measures are employed, in addition to injections of the antitoxin. The lids are frequently everted, and the false membrane gently touched with swabs of cotton wet with a 1–500 solution of mercuric chlorid. Into the conjunctival cul-de-sac is introduced a small quantity of an ointment containing a sixth of a grain of mercuric chlorid to the ounce of vaselin. Over the closed eyelids are placed compresses saturated with a solution of mercuric chlorid 1–1000, or of boric acid fifteen grains to the ounce. The use of cold compresses and astringent antiseptics is contraindicated. Corneal ulcerations are touched with a solution of mercuric chlorid 1–1000. Secondary eczemas are treated with solutions of silver nitrate, fifteen grains to the ounce.—*Semaine Médicale*, 1896, No. 30.

The Treatment of Gonorrhea With Formaldehyde.—Orloff (*Wratsch*, 714, 1895; *Centralbl. f. d. Krankh. d. Harn- u. Sexual-Organe*, B. vii, H. 5, S. 287) details the results secured in the treatment of ten cases with formaldehyde. Following injections of a five per cent., or a weaker solution, the purulent secretion soon became serous and gonococci disappeared. Unpleasant effects were not observed. As formaldehyde is volatile, it is well always to prepare a fresh solution. Stronger solutions than five per cent. are not to be recommended.

SATURDAY, OCTOBER 3, 1896.

BROOKLYN'S DANGER AND THE INADEQUACY OF HER CHARITY HOSPITAL.

The condition of Brooklyn's water supply has occasioned no little concern among her inhabitants during the last few weeks. It required an unreasonable length of time to arouse the proper authorities to a realizing sense of the situation. The wonder is that the people were willing to use such a discolored, foul-smelling water, without prompter protest. The only explanation can be found in the fact that Brooklyn has long prided herself upon the excellence of her water supply. Backed by the sweeping assertions of her chemists, announced years ago, that Long Island afforded an unfailing supply of the purest and best water in the world, she has been innocently resting upon this assurance, and denouncing as an ignoramus anyone who dared intimate that Brooklyn water was not the purest. In the meantime, Long Island has been rapidly peopled by a surprisingly large population, which has naturally congregated in the greatest numbers along her water courses, and now that Brooklyn water is foul and malodorous, the citizens are awakening to the condition that confronts them. With the many sources of contamination that surround the sources of her water supply, from the drainage attendant upon this increasing population, it is a matter for thankfulness that germs, productive of fatal epidemic, have not already found their way in the water channels.

As recorded in the News of last week, the careful analysis of many specimens of the water taken from the various sources of supply, fails to discover any cause of disease therein, the expert who examined them announcing that there is no danger in the use of the water "at present." But he did find a condition to exist, which undoubtedly affords a most fertile nidus for the develment of typhoid and other noxious germs.

Until this can be eradicated, the dangers and the horrors of a typhoid-fever epidemic constantly threaten with the imminence of the sword of Damocles. How promptly and how thoroughly the cleansing of the waters shall be accomplished is a question of the future. For the present, the urgent question that suggests itself is, how well is the charity hospital of Brooklyn equipped to meet an epidemic should it arise?

A personal investigation, on the part of the News, discloses the fact, that not only is the city utterly unable to cope with an epidemic, but that her present accommodations for the sick poor already existing within her limits and demanding care, are shamefully inadequate. We have read, in the years happily long since past, of the overcrowded condition of the French hospitals, wherein the revolting spectacle was presented of four patients, afflicted with different diseases, crowded crosswise into two single beds placed side by side, whole wards being filled in this way. To our utter amazement, we find Flatbush Hospital in Brooklyn, in quite a similar condition.

Flatbush Hospital, the only public hospital in the city, was erected forty or fifty years ago, with accommodations for four hundred patients. But the building that filled the requirements of fifty or even twenty years ago, has been rendered utterly inadequate by the great increase in the city's population. The result is that a building intended to accommodate four hundred, is compelled to give shelter to seven hundred. That is the number actually crowded into the existing

space. No doubt the good people of Brooklyn will be horrified to learn that if they should enter the portals of the Hospital, they would find from three hundred to three hundred and fifty of their sick poor bestowed on mattresses laid on the floor. To add to the discomfort occasioned by this disgraceful condition, there is not a trained nurse in the institution, and the efficiency of such nurses as there are can be imagined, when we learn that they are obliged to sleep in the wards with the patients. Necessarily, the sanitary and hygienic arrangements are insufficient to meet this extraordinary demand. The medical staff, under efficient leadership, are struggling manfully against overwhelming odds, to render the best service possible under the circumstances.

That such a wretched condition should exist, at this stage of enlightenment in regard to hospital accommodations and management, is a blot upon the reputation of any community.

RECENT PROGRESS IN NEUROLOGY.

CEREBRAL HISTOLOGY AND ANATOMICO-PHYSIOLOGY.

Neurological literature for the past few years has reflected very little which possessed either novelty or special interest in the domain of gross anatomy or histology, but in the more delicate and still somewhat obscure field of minute histology and anatomico-physiological research much work has been done, with a resultant degree of enlightenment which is prophetic of a rich harvest in the near future. The factor chiefly responsible for our advancement in this direction has been the various improvements devised in methods of research, the most notable of which are associated with the names of Golgi, Luciani, Marchi, and Ramon y Cajal. Other workers in this field, whose contributions have added notably to the value and scope of our knowledge of the subject are Andriezen, Risien Russell, Mellus, Van Gehucten, Turner, Schaeffer, Bevan Lewis, Biedl, and Chaslin.

The line of investigation which has been most positively fruitful in results has been that of experimentally induced pathology. Beginning with the functionally highest structures, the cells of the cortex, Andriezen has shown that the apical processes of the great pyramidal cells of this region receive the terminal processes of the fillet radiations, a fact which leads to the conclusion that these are the sensory cells of the cortex. If accepted, this conclusion points to the correlated acceptance of a practically identical cortical localization of motor and sensory function or representation. Further support of this teaching is to be found in the results obtained through experimental studies by Flood and Schaeffer (*British Med. Journal*, July 28, 1894). With very few exceptions, this view is generally accepted among neurologists to-day. In connection with this subject of cerebral representation of common sensation, Spitzka (*Lancet*, January 19, 1895) publishes advance notes of a case of direct interest and importance, involving a focal lesion of the right stratum intermedium, the patient presenting during life more or less complete right hemianesthesia, with loss of mechanical coördination, but preservation of equilibrium. Further study, not yet complete in this case, is expected to demonstrate facts of importance in connection with the pathway of sensory fibers in the cerebrum. Turner's (*Brain*, 70, 71, 1895) experiments, several in number, also bear upon this subject of the pathway of fibers conducting sensory impressions. He destroyed the tubercle of Rolando in the medulla of the monkey, and noted as a result (1) defect or abolition of all forms of sensation in the skin, mucous membrane, and cornea supplied by the fifth nerve, with contraction of the pupil of the same side, but without trophic change in the eye. The loss of sensibility was in relation to destruction of the ascending trigeminal root forming the superficial white stratum of the tubercle. The effect on sensation in the body was (2) loss or defect of the sense of touch and of localization on the side of the lesion, but retained pain-sense, while on the side opposite, the impairment was of pain-sense only.

Mellus (communication to Royal Society, England), working in the laboratory of Horsley, reports the results of a series of experiments made with the object of determining the pathway of certain motor fibers from the cortex downward. The bonnet-monkey was the subject of experiment, the centers for the hallux, thumb, and face

in the left hemisphere being the areas of the cortex subjected to minute experimental lesions. He found that the coarser degenerate associate fibers from the thumb lesion were distributed to the upper part of the motor area, and the finer fibers to the lower—an observation corroborative of the measurements of Bevan Lewis. In the internal capsule these degenerate fibers were divisible into two systems, one the fine fibers passing into the outer surface of the optic thalamus from the posterior limb of the capsule; the other, coarse fibers, passing through the internal capsule into the crus and ending, apparently, in the *substantia nigra*. The fibers representing degeneration secondary to the lesions of the facial center are situated in the middle third of the crus, mingled with the fibers of the pyramid, and not occupying a separate space mesial to the pyramid. These experimental findings are especially noteworthy, since they, in some degree, are opposed to the teachings of Meynert and others.

The pituitary body, long an enigma as regards its function, has been the subject of especial study by Andriezen (*British Med. Journal*, January 13, 1894) and Sacchi and Vassali (*Centralbl. f. Allgem. Path. Anat.*, May, 1894). They find that the function of this body is essentially trophic, enabling the nerve-tissues to take up and assimilate oxygen from the blood-stream. It also exerts an influence upon metabolism, destroying or rendering innocuous certain waste products. The pathological findings in acromegaly involving disease, usually of hypertrophic type, of this gland are strongly confirmatory of the experimental findings of Andriezen.

The cerebellum has perhaps been the subject of more extended and enthusiastic study than any other special portion of the cerebro-spinal system during the past half decade. Marchi, Luciani, Risien Russell (*British Med. Journal*, July 28, 1894), Turner (*British Med. Journal*, August 21, 1894), Biedl, and Ferrier are among the large number who have made notable contributions to our present knowledge of the subject. Ferrier (*Annual of Univ. Med. Sciences*, 1895, vol. 2; Section, Brain), in his presidential address before the London Neurological Society, reviews critically the published researches in this field of Luciani and Marchi. He accepts as proven by them the facts: (1) That the cerebellum has no share in psychical manifestations; (2) its removal causes no evident impairment of any of the special senses, nor cutaneous nor muscular sensibility; (3) it has nothing to do with sexual impulse or desire; (4) the influence of the cerebellum is direct and not crossed; (5) the middle lobe is not, as taught by Nothnagel, the essential lobe. Some of these statements, as will be noted, are radical innovations in teaching and belief.

William Broaddus Pritchard, M.D.

ECHOES AND NEWS.

Diphtheria in Iowa.—The county fair has been abandoned, and the public schools have been closed on account of an epidemic of diphtheria in Salem, Iowa.

Cycling for the Insane.—Bicycle riding has been introduced into the Michigan Insane Asylum at Kalamazoo, for its beneficial effects on the patients.

Whooping-cough in an Orphan Asylum.—Whooping-cough is epidemic in the Colored Orphan Asylum, New York, which has upward of two hundred inmates. The institution has been quarantined.

Disease in Cuba.—There has been a notable increase of yellow fever among the Spanish troops in Cuba. There are upward of 2500 patients in the Military Hospital at Havana.

The Cholera in Egypt.—The weekly mortality from cholera throughout Egypt has fallen from two thousand to six hundred. It is expected that in November or December the epidemic will be entirely eradicated.

Irrigation of the Pericardial Sac.—Professor Verdelli of Parma, recently opened the thoracic cavity, exposing the pericardium, which was given an antiseptic washing. The patient, who had been given up as lost, recovered.

Opening of the Samaritan Hospital Annex.—The annex to the Samaritan Hospital in Philadelphia was opened on September 26th. The new building cost $10,000, and will accommodate twenty-six patients.

Antitoxin for Lockjaw in Brooklyn.—Dr. Ezra Wilson, the bacteriologist of the Brooklyn Health Department, has been preparing tetanus antitoxin. It has been used with apparent success in a case this week.

A Layman as a Public Vaccinator.—The government of South Australia, whose attacks on the medical profession led to the resignation of the staff of the Adelaide Hospital, has appointed a layman as a public vaccinator for the colony.

The Bubonic Plague.—A virulent bubonic plague is prevalent in many parts of the Bombay Presidency, from

which upward of a hundred deaths have already resulted. There are only sporadic cases of the plague now in Hongkong.

Eberth's Bacillus.—Drs. Remlinger and Schneider of the Val-de-Grace Bacteriological Laboratory, have found Eberth's bacillus to be much more common than was generally supposed. It was present in eight out of thirty-six samples of water, and in six out of ten samples of earth.

Displacement of the Heart.—A seventeen-year-old girl died recently at the New York Hospital. The autopsy showed that in childhood the central lobe of her right lung had collapsed and the fatty growth that resulted caused an adhesion of the heart to the wasted tissues on the right side.

The New York State Veterinary College.—The State Veterinary College at Cornell University, was opened September 23d. The State Legislature of 1894 appropriated altogether $250,000 for the erection of the college buildings, and since then $30,000 has been appropriated for its annual maintenance.

Good Work Among Mohammedan Women.—A recent issue of the *Med. Wochenschrift* describes the reforms introduced into Bosnia and Herzegovina by two women physicians, Drs. Krayeska and Keck. By reason of their sex they have won the confidence of the Mohammedan women and, by their antiseptic obstetrical work, have reduced the mortality of these provinces to a gratifying extent.

Typhoid in Chicago.—Secretary Reilly of the Chicago Health Commission predicts an epidemic of typhoid fever unless citizens are more careful in the use of the water. Thus far in September there have been 64 deaths from typhoid, and there are said to be over 600 cases of the disease in the city. The typhoid fever death-rate shows that there were at least 600 cases in August.

Money to Purify Brooklyn's Water.—The Brooklyn Board of Aldermen at its session, September 21st, adopted the report of the Committee on Water and Drainage, which gives the Commissioner of City Works $311,000 for the maintenance of the water system, $150,000 for diverting the dirty water from Hempstead Reservoir, and $75,000 for the purchase of land to protect the water supply. The purification of Gowanus Canal was also considered.

Sleep Experiments.—Professor Patrick and Dr. J. S. Gilbert of the University of Iowa, in the *Psychological Review*, record experiments made to determine the effects of prolonged loss of sleep. Dr. Gilbert and two of the University teachers were kept awake for four days and three nights. One suffered most on the second night, another on the third, the other experimenter was not affected. All gained in weight. The power to lift, steadily decreased, and memory and power of attention were also lessened. All powers were completely restored after a sleep of eight or ten hours.

A Baltimore Bequest.—The bulk of the estate of the late Enoch Pratt, the Baltimore banker and philanthropist, is left to the trustees of the Sheppard Asylum of that city, with the stipulation that the name of the institution be changed to the Sheppard and Enoch Pratt Hospital. The income of the fund is to be used to complete the present buildings and grounds, and erect an additional building, with a capacity for two hundred persons. When this is done the remaining fund is to be used for the care of indigent insane free of cost. The bequest is made on the contingency that the trustees obtain an act to amend the charter of the institution.

New Edition of "Gray's Anatomy."—A copy of the revised edition of "Gray's Anatomy," recently announced by Lea Brothers & Co., has just been received. Much expectation was aroused by the announcement, and the appearance of the volume meets it most fully. The pages look familiar, as we turn them over, but many of the subjects have been entirely rewritten and some new matter added. The addition of 135 new and handsome engravings enriches the volume beyond what seemed possible. By the addition of this artistic work "Gray's Anatomy" easily holds its place as "the foremost of all medical text-books." A fuller review will appear in the columns of the NEWS very shortly.

Bacteria and Aerated Water.—Professor Frankland, in *Nature*, shows the fallaciousness of the prevalent idea that by drinking aerated water safety from infectious diseases is insured. In experiments by Slater, the number of bacteria varied from 299 per cubic centimeter with 15 grams of carbon dioxid per liter, to 2000 with 6 grams per liter. The spores of the anthrax bacillus have been found to survive 154 days in aerated water, but the cholera bacilli cannot live longer than three hours. The typhoid bacillus requires a period of two weeks to insure its destruction. The author recommends storage for a certain period, as time is thereby given for the destruction of the pathogenic bacilli by the innocuous forms.

The Water Supply of the League Island Navy Yard.—The report of Surgeon Siegfried of the U. S. battleship "Massachusetts," alluded to in our issue of the 19th, is vigorously disputed by the Board of Health of Philadelphia. They deny that the League Island Navy Yard possesses any connection with the city mains, and assert that the drinking-water used there is obtained from a local system, the sources of which are driven wells. It is further stated that the surgeons at League Island have frequently reported that the conditions at that yard are detrimental to the health of officers and men stationed there, and that it is the duty of the U. S. Bureau of Medicine and Surgery to take such measures as will prevent disease at the naval stations.

International Registration of Scientific Discoveries.—Professor Michael Foster of Cambridge University, has proposed an international organization of science to register at frequent intervals the results of contemporary investigation, and so by placing the worker and his output on record to minimize the risk of retracing ground already trodden, and to make clear to the world of science what has already become common property and what still re-

mains the possession of the original author. If this plan can be adopted there will, of course, be fewer cases of disputed priority in regard to private as well as laboratory experimentations and discoveries. Suits for plagiarism, like that of the French dentist against Professor Lombroso—not frequent at the present time, it is true—will become exceedingly rare.

Obituary.—John Eric Erichsen, F.R.S., LL.D., Hon. M.Ch. and Hon.F.R.C.S., died at Folkestone, England, September 23d. He was born July 19, 1818, and educated at the Mansion House, Hammersmith, and at University College, London, At the time of his death Mr. Erichsen was Emeritus Professor of Surgery and consulting surgeon to University Hospital, and to many other medical charities. He had been President of the Royal College of Surgeons of England, of the Royal Medical and Chirurgical Society, and of the Surgical Section of the Great International Medical Congress of 1881. He was Surgeon-Extraordinary to the Queen, and had been President of University College, London, since 1887. Mr. Erichsen was the author of many works and essays on physiology and surgery.

The "New Journalism" Transplanted.—"The Lounger" writes in *The Critic:* "Display headlines give the London *Daily Mail* quite the air of an American newspaper . . . That the sensational aspect imparted by the glaring headlines does not always belie the text, is clearly shown in its cablegrams from America. Under date of August 14th, for instance, its New York correspondent sent this dispatch: 'Still the heat continues, and the odor of the charnel-house reigns over the city. From hundreds of decomposing human bodies, and from the rotting carcasses of horses there exhales a stench that is positively sickening. Added to this horror is an epidemic of rabies. Mad dogs are running about the streets, and already more than a score of children have been bitten. The mortality due to the heat yesterday totals up eighty-five persons.'"

NEW YORK FOUNDLING HOSPITAL — RESOLUTIONS ON THE DEATH OF SISTER IRENE.

The Medical Board desire to pay tribute to the memory of Sister M. Irene FitzGibbon, late Superior of this institution.

Several members of the Board have served for more than twenty years, and have witnessed the growth of this work, its transference to larger buildings, and its full development.

They recognize the fact that the one person who organized, who procured friends and funds, who planned and built the one great Foundling Hospital of America, was Sister M. Irene.

Whatever other forces and agencies were assisting, it has been obvious to all that the central figure, the persuasive tactful genius, the sweet-souled woman who led to this success, was she to whom to-day the Medical Board pay this parting tribute:

Whereas, the Medical Board, in the death of Sister M. Irene, the Sister Superior of the Hospital, have lost the first executive officer and long-tried friend, therefore be it

Resolved that the Board cause to be spread upon the minutes of its records these resolutions of appreciation and sorrow, incorporating the words:

"This Board has lost the best friend any hospital board ever had."

Resolved further, that the sympathy of the Board be extended to the Reverend Mother Superior and the Sisterhood of the Sisters of Charity, also that a copy of these resolutions be forwarded them, and be published in the current medical periodicals.

New York Foundling Hospital, September 15, 1896, special meeting. Signed

J. Lewis Smith, M.D. J. O'Dwyer, M.D.
George F. Carey, M.D.,
President of the Medical Board.

SOCIETY PROCEEDINGS.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-second Annual Meeting, held at St. Paul, September 15, 16, 17, and 18, 1896.

The Association convened in the Senate Chamber at the Capitol.

PRESIDENT'S ADDRESS.

Henry O. Walker, M.D., of Detroit, delivered the president's address. He reported three cases, in which four operations were done, representing nearly all the operative procedures now done upon the kidney.

Case I was of sacculated kidney with suppuration and nephrolithiasis, and nephrolithotomy, and subsequent nephrectomy.

Case II was of tubercular kidney and nuclein treatment.

In Case III there was a freely movable tumor in the right hypochondriac region. The kidney was placed in its proper position, and the capsule divided for a distance of three inches on its convexity, using care not to wound the cortical substance. The capsule was then separated from the kidney for one inch entirely around the cut, and secured by interrupted catgut sutures. The cut edges were fastened to the fascia and muscle, so that when the suturing was complete, there was a solidity of fixation of the kidney.

Truman W. Brophy, M.D., of Chicago, read a paper on

A NEW OPERATION FOR CLEFT PALATE.

It has usually not been thought advisable to operate for the closure of cleft palate until the child is from two to five years old. He maintained that when the operation was thus postponed, the changes in the voice had become permanent, and a repair of the cleft at that time would not react favorably in the voice-production. He freshens the edges of the cleft, then by deep suture of the silver wire fixed through a lead plate, conforming to the palate, draws them together.

C. H. Hughes, M.D., of St. Louis, Mo., read a paper on

THE PSYCHO-NEURAL FACTOR IN CLINICAL MEDICINE.

The physician must consider the whole mechanism of the system when treating any one part. The surgeon must consider the susceptibility, predisposition, powers of resistance, recuperative powers, and natural courage of the patient in determining as to the prognosis or operation. Painful ovaries, neuralgic, congested, or inflamed, are not necessarily to be cut out, but to be cured by neurological treatment. Hope is itself a buoyant medicine, and faith in the physician or surgeon is a therapeutic power that should never be shattered by us.

HUGH T. PATRICK, M.D., of Chicago, read a paper on

TRUNK ANESTHESIA IN LOCOMOTOR ATAXIA.

In nearly all cases of tabes dorsalis there is a band of anesthesia about the trunk at the level of the nipple. It is, early in the disease, very narrow or even incomplete, or may be represented by a zone in which the localization of touches is not normally accurate. The sensory blunting on the leg, so frequent in tabes, is generally an analgesia. The trunk anesthesia is essentially tactile, and the pain-sense may be quite normal. The band of anesthesia does not correspond to the cutaneous distribution of the intercostal nerves, but to the nerve-fibers arising from adjoining segments of the spinal cord. In some cases there are two distinct zones of anesthesia, indicating simultaneous involvement of spinal segments at some distance from each other. The borders are inconstant, ordinarily retract on continued testing, and vary in position with the method of examination. The same band of anesthesia may occur in syphilitic pseudo-tabes, as shown by an illustrative case, as far as known, the only one on record. The patient presented nearly all the symptoms of locomotor ataxia, including a wide band of trunk anesthesia, but a diagnosis of syphilitic disease of the cord was made, and, under an active specific treatment, he made an almost perfect recovery.

DR. HUGHES said that it was not surprising that these peculiar areas of anesthesia should be found in locomotor ataxia, considering that the entire symptom complex of the disease is due to disturbance of the sensory mechanism. He has long taught that organic disease may give expression to a latent hysteria, causing a combination of the two diseases. In locomotor ataxia may be not only anesthesia and analgesia but also hyperesthesia and hyperalgesia.

GUSTAVUS BLECH, M.D., of Detroit, read a paper on the

TREATMENT OF SOME INFLAMMATORY DISEASES OF THE GASTRO-INTESTINAL TRACT.

Treatment of catarrh of the stomach and similar inflammatory conditions, as practised to-day by most medical men, meets with failure because the treatment is directed against the symptoms and not against the cause of the disease. His treatment is directed against the inflammation itself. He prescribes hydrozone, well diluted in water, at least a quarter of an hour before each meal. The oxygen, which then develops, kills the germs, and cleanses the membrane of the wall of the stomach without injuring the animal cells. It is an efficient and powerful, yet bland and innocent remedy. He explained the cure of a case of gastric ulcer with the above treatment.

DR. DALEY of Pittsburg, deprecated the very general use of glycozone, hydrozone, and such remedies, unless a very careful and discriminating diagnosis had been made. Most of the cases are due largely to the formation of toxins.

DR. F. F. LAWRENCE suggested that gastritis was sometimes due to gall-stones.

DR. I. A. ABT of Chicago said that diseases of the stomach cannot be grouped together as gastritis. Many of these conditions are due to toxins found in the gastro-intestinal tract.

DR. LARRABEE of Louisville, is convinced that the portal circulation is a most important factor in these cases, and one, too, which is often overlooked. Exercise is of paramount importance, in all cases of chronic gastritis. In arresting putrefactive changes in the stomach, glycozone has proven most excellent in his hands, but he does not neglect to stimulate the liver when indicated.

PAUL PAQUIN, M.D., of St. Louis, read a paper entitled

THE TREATMENT OF EXPERIMENTAL TUBERCULOSIS IN ANIMALS BY THE USE OF BLOOD-SERUM.

In guinea-pigs inoculated with tuberculosis and then treated with serum, ten per cent. were saved. Later results show a very much higher percentage than this, from twenty-five to fifty-five per cent, being favorable. In human beings, 226 cases showed about sixty per cent. favorable, with 40 recoveries and 120 improved. Anti-tubercle serum is positively curative in many cases. If it does not succeed, it is because of existing conditions, such as intolerance of serum-injections of any kind (which is very rare), general destruction of physiologic equilibrium beyond repair, incurable lesions or mixed infection.

DR. LONGSTREET TAYLOR of St. Paul: It is not necessary that the serum should produce an antitoxin in the body. It will, in many cases, give most gratifying results, but in others, for some reason, it is just as disappointing. His experience with the Paquin serum had not been entirely satisfactory, but he intended to give it further tests.

DR. H. W. LOEB of St. Louis had presented some reports relative to the treatment of laryngeal tuberculosis with serum. Of the cases reported, at least two are yet living and well. Of two others, he could not say, but at latest reports there was no return.

DR. JOSEPH MUIR of New York, is convinced a change in the home surroundings of many cases will do more toward a cure than a change of climate.

E. M. HOUGHTON, M.D., of Detroit, read a paper on

A DEMONSTRATION OF THE THERAPEUTIC ACTION OF THE ANTITOXINS.

He reviewed the theories of serumtherapy, demonstrating the differences between toxins and antitoxins. It has not as yet been shown just how the antitoxin counteracts or destroys the toxin. He brought six guinea-pigs for demonstration, three of which he injected with the toxin cultures, the other three with the antitoxin and toxin.

The discussion of the paper was postponed until the result of the injection on the animals should be determined.

Joseph Muir, M.D., of New York, read a paper on

REINFECTION IN CONSUMPTION.

Statistics show that a first attack is not always fatal, and death is often found to be due to other causes. Primary infection is not usually due to inherited tendencies, but external conditions play a most important part. Consumption is best treated among the rich, frequently indeed, a permanent cure is effected in this class of cases; so, for evident reasons, those who are poor should be given especial attention. Patients who have been cured must not be allowed to return to their former environment. Redevelopment is inconsistent with clinical experience. Change of air and outdoor exercise and labor hardens and refreshes the tissues, and the respiratory impurities of former environment are no longer present. Reinfection may be prevented by thorough disinfection of the patient and surroundings, and destruction of the sputum. This protects the patient against himself.

Dr. H. J. O'Brien of St. Paul, is satisfied there are many cases of reinfection. By staying away patients will sometimes escape contagion and reinfection.

Dr. J. A. Larrabee of Louisville, has long believed that if a consumptive could have proper conveniences and care in the beginning, along with high feeding, the disease could be entirely checked or aborted in many cases. The most terrible mistake is made in sending subjects away for treatment. Home is best, no matter where that home is. Improve it all that is possible, but leave the sufferers among friends.

J. B. Murphy, M.D., of Chicago, read a paper on

INDICATIONS FOR, AND DEMONSTRATIONS OF, REMOVAL OF GASSERIAN GANGLION.

He demonstrated the technic of the operation on a cadaver head. The operation may seem heroic, but heroic measures are necessary in a condition so severe as trigeminal or facial neuralgia. These patients will submit to anything in the hope of relief. Indeed, they have said before the operation, "Doctor, either kill or cure me." He has always suggested some conditional treatment, especially that of castor oil before resorting to so heroic and serious a measure as this operation. This has given temporary relief in several cases.

Dr. A. J. Ochsner, Chicago, had recently given castor oil in cases of facial neuralgia in half-ounce doses, twice daily for ten days or two weeks at a time, and it has thus far proven a most efficient remedy. No case has yet returned to its former severity.

Hugh T. Patrick, M.D., Chicago, read a paper on

ELECTRO-DIAGNOSIS AND ELECTRO-THERAPEUTICS SIMPLIFIED.

Electro-diagnosis is limited to the affirmation or denial of a lesion of the lower neuron; that is, of a lesion of the motor cells in the spinal cord, or of the nerve-fiber, the peripheral nerves springing from those cells. A lesion of this neuron causes the action of degeneration, and this may be recognized by a loss or very considerable diminution of faradic contractions, and by the slow wormlike contraction of the muscles to interruption of the galvanic current. In the electro-therapeutics of organic disease of the nervous system, applications of electricity through the brain may be entirely discarded as useless. Electricity through the spinal cord is little better. In diseases of the peripheral nerves it probably hastens recovery, and that current is to be chosen which better causes muscular contraction. In functional nervous disease electricity is of more practical value than in organic affections, but it is almost impossible to determine what proportion of this good effect is due to mental impression—to suggestion. The galvanic current is chosen for facial and costal neuralgia and sciatica; the faradic for lumbago, hysterical anesthesia, paralysis, and pain; the galvanic for exophthalmic goiter, and sometimes for neurasthenic headache, and backache. For facial spasms, tic, spasmodic torticollis, tremor, and chorea, electricity is useful, aside from the mental effect.

J. Frank, M.D., of Chicago, read a paper on

A NEW METHOD OF FASTENING THE ROUND LIGAMENT IN ALEXANDER'S OPERATION.

An incision an inch long is made midway between the anterior superior spine of the ilium and the spine of the pubes, a trifle above Poupart's ligament. The transversalis muscle is pushed back and the ligament lifted out with a blunt hook. Draw it out until the uterus is in the correct position. Instead of drawing the ligament through the fascia, as formerly practised, it is replaced in its anatomical position beneath the transversalis muscle. By this method a slough of the ligament is prevented. This operation is the simplest of all yet proposed for the purpose. As a suture-material, kangaroo-tendon has proven most satisfactory in his experience. A pessary should be fitted in before the operation, and worn as long afterward as may be deemed necessary by the surgeon.

J. Homer Coulter, M.D., of Chicago, read a paper on

TONSILLOTOMY BY CAUTERY DISSECTION.

With a well-heated, small electro the pillars are dissected away from the tonsil to one-half its extent. The gland is then, with suitable forceps, drawn well out and dissected out to about one-half its extent. This portion is then cut off and the surface treated with a strong solution of silver nitrate. In a week or ten days the other portion of the tonsil is removed in the same manner. This operation will give cosmetic as well as practical results, unobtainable by any other process yet suggested.

Dr. H. W. Loeb of St. Louis, instead of performing so much dissection, removes as much of the tissue as he can get in an electric snare. This is repeated as often as may be necessary to remove all the glandular substance. He thinks the method causes less soreness and less pain than that of Dr. Coulter, and in many cases, particularly children, the results will be just as satisfactory.

W. J. Mayo, M.D., of Rochester, Minn., read a paper entitled

THE SURGICAL TREATMENT OF PYLORIC OBSTRUCTIONS.

He has found the free exhibition of strychnia for several days previous to the operation of great value in preventing

shock. The stomach should always be thoroughly washed out a few hours before the operation, and nothing eaten afterward. For combating the shock, besides strychnia and dry heat, a rectal enema of a pint of hot coffee should be given. Nourishment by the stomach should not be too long withheld afterward. For twenty-four hours rectal alimentation should be used; in thirty-six hours, some champagne; later, buttermilk and a gradually increasing diet.

Dr. A. F. House, Cleveland, opposed the use of the Murphy button, and did not consider it the ideal method, as his experience has been somewhat unsatisfactory. He believed the less foreign matter one gets in the wound in uniting the bowel to the stomach, the better the result.

Dr. A. J. Ochsner, in some twenty cases, had used irrigation of the stomach with decided satisfaction. In this way the patient will sometimes become well enough nourished to stand an operation when it is desirable.

Thos. H. Manley, M.D., of New York, read a paper on

CONDITIONS WHICH MAY SIMULATE ORGANIC OBSTRUCTION OF THE RECTUM.

Norval H. Pierce, M.D., of Chicago, read a paper on

SUBMUCOUS LINEAR CAUTERIZATION; A NEW METHOD FOR REDUCTION OF HYPERTROPHIES OF THE CONCHÆ.

A small incision is made in the hypertrophied membrane; then, with a blunt, flat probe the mucous membrane is carefully separated from the erectile tissue underneath. A sound, the end of which is cup-shaped, and upon which has been fused a few crystals of chromic acid, is inserted in the incision and the track already made by the probe is thus cauterized. There is no hemorrhage and less pain than by any other method. The functional activity of the mucous membrane is not in the least impaired. Patients will submit to this operation more willingly than to the burning of the cautery.

Dr. Coulter suggested the possibility of the chromic acid being left within the operative field, in which case an undesirable slough would necessarily follow. The practice of many rhinologists in using a broad, flat electrode, and destroying a large amount of the mucous membrane, and in not going down to the bone, is to be deplored, as irrational, unscientific, and impracticable.

Dr. H. W. Loeb, St. Louis, had seen blindness result from cauterization of the inferior turbinates, and wished to know if there was danger in the use of the chromic acid.

Dr. Stuckey is able to get the same results as from cocain, without danger and with less systemic disturbance, by the use of a harmless solution of acetanilid.

Dr. Love wished to enter a protest against the indiscriminate and carelesss use of cocain in the nose. There are going about the country to-day hundreds of men and women, miserable victims of the medical profession's careless use of cocain.

Horace H. Grant, M.D., of Louisville, selected for the address on surgery

THE RELATION OF DIAGNOSIS TO FUTURE SURGICAL PROGRESS.

We cannot progress much farther in technic or operative skill. Any great amount of paraphernalia suggests a lack of personal resource in the operator. Almost every part and organ of the human body has been removed. The skiagraph has lately come into importance in surgical work, and it may be an excellent adjunct in many instances. Its recent successes are noteworthy. It is yet, however, in its infancy, and doubtless is capable of still more development. May we not soon expect to see the fetus in utero? No one doorway can open to the royal road to success in the practice of surgery. The skilful and intelligent application of prompt relief, added to a careful diagnosis, will give us the most wonderful and satisfactory results. What each one finds to do, let him do it with his might.

Jas. H. Dunn, M.D., of Minneapolis, presented a paper on

APPENDICITIS; TO OPERATE OR NOT TO OPERATE?

If it were possible to foretell which cases were going to be fatal, this question could be much more easily and satisfactorily decided. The percentage of fatality is yet too high. A certain number of cases will recover without surgical interference. Indeed there is so large a number of such that he believed we very often, in our enthusiasm, operated when it would have been much better to have left them alone, so far as the knife was concerned.

Dr. J. B. Murphy said that in 450 cases he did not think there had been an entire absence of pus in a single instance. He was satisfied there are some cases which can be cured by medicine, but can they be differentiated? By medical treatment we have a mortality of ten per cent., and if we have three per cent. by the knife, then we must operate to save the other seven per cent. Conditions will show whether or not an operation is advisable.

Gustave Futterer, M.D., of Chicago, read a paper on

PLEURITIC EFFUSIONS AND THEIR TREATMENT.

A bacteriological examination should be made in all cases, both with cover-glasses, with culture-media, and by injections of the effusion in animals. Distinguish between exudate and transudate by using the acetic-acid chemical test, and by the same process eliminate mucin. Many cases of pleurisy are of an uric-acid diathesis. These will yield readily to the treatment by the salicylates. He believes that not more than fifteen per cent. of pleuritic cases are rheumatic. The finding of pneumococci does not aggravate the conditions, and often gives no markedly distinct symptoms. Pleurisy in typhoid is not a mixed infection, but a distinct condition. Tubercle bacilli are often found in the pleuritic effusions. Tuberculosis may be differentiated by the agar culture. Hyperesthesia of different parts is frequently present. He has washed out the cavity in fourteen cases with an antiseptic solution of from one-half to two per cent. of clove oil, with gratifying results in twelve of the cases. The advantages of this method are: Many patients will allow such an operation, who would object to an exsection of the rib; no

bulky dressings are constantly interfering with the comfort and convenience of both patient and physician; much shorter time is required.

A. J. Ochsner, M.D., of Chicago, read a paper on

NERVE SUTURES AND OTHER OPERATIONS FOR INJURIES TO THE NERVES OF THE UPPER EXTREMITY.

His conclusions were: (1) Every severed nerve should be sutured even after years. (2) The earlier the operation is performed the better. (3) If neither sensation nor motion is established within a year, the nerve should again be exposed, the cicatricial tissue removed and the end again sutured. (4) The end should be clean-cut, and should contain neither crushed nor cicatricial tissue. (5) Tension must be avoided. (6) The wound must heal without suppuration to secure the best results. (7) Hemorrhage should be perfectly controlled to prevent intervening clot. (8) Carefully prepared catgut is the best suture-material. (9) After suturing the ends, either direct or "a distance," it is well to stitch a fold of fascia over the united nerve-ends. (10) The extremity should be placed at rest. (11) The external incision should be ample,

Henry P. Newman, M.D., of Chicago, read a paper on

WOMAN AND HER DISEASES, VERSUS GYNECOLOGY.

We are coming to a period of transition in the practice of surgical gynecology; instead of essays on the treatment, there are studies on the cure and prevention. Preventive medicine, hygiene, sanitation, and sociology are now popular themes for medical societies. Philanthropy has taken the cue from medicine, and is attempting to form a citizen rather than reform him. Woman's sphere has lately widened, until now it is as wide as man's. Has she equipped herself for this race intelligently? Look at the average woman in the cities; the average stenographer, saleswoman, the business woman, do they not daily outrage their bodies by compliance with the dictates of fashion in food, dress, and habits? A woman's generative organs should not be doomed because she has needed to visit the gynecologist. A good diagnostician must know as much about women as about disease, as much about environment and social and domestic relations as about pelvic lesions. Gynecologists should lead in the reform of those conditions which are detrimental to the health of woman.

F. F. Lawrence, M.D., read a paper on

THE PATHOLOGY AND TREATMENT OF SUPPURATIVE SALPINGITIS.

Seldom will vaginal section be required, and only in carefully selected cases. Hysterectomy is indicated in those cases where abscess of the uterine wall, tuberculous deposits, fibroids, or malignant disease in the fundus are found. As hysterectomy destroys the pelvic floor, it should never be performed except where there is some tangible lesion of the uterus. Abdominal section will be necessary in many cases.

James B. Herrick, M.D., of Chicago, contributed a paper on

THE IMPORTANCE OF PHYSICAL SIGNS OTHER THAN MURMUR, IN THE DIAGNOSIS OF VALVULAR DISEASE OF THE HEART.

Practically, conclusions are usually based upon the presence or absence of endocardial murmurs. This is wrong, for there may be a valvular disease without a distinct murmur being audible. Every valvular lesion must result in hypertrophy and dilatation of the heart behind the valve diseased. An increase in tension of the pulmonary circulation follows any valvular lesion at the mitral orifice and, later, any aortic disease. This will show in increased force of the pulmonic second tone. Stenosis of the orifices of the left heart means a smaller amount of blood in the general arterial circulation, therefore lesened arterial tension. Failure of the right heart is followed by venous congestion, *e.g.*, venous pulse, hepatic and portal congestion, anasarca, etc. Hypertrophy may be recognized by the heaving, forcible, apex-impulse. Epigastric pulsation may call attention to enlarged right heart. The jugular pulse, the hepatic and capillary pulse, are all of diagnostic value. The visible pulse of aortic regurgitation is almost pathognomonic. Palpation is important. Extracardiac causes for murmur, such as might arise in a heart dislocated by pressure or retraction, can usually be excluded by percussion. A weak, aortic sound may be an indication of obstruction. The reduplicated second sound may point to valvular disease. A sharply accentuated first sound at the apex is common in mitral stenosis. The peripheral tones in aortic regurgitation are a valuable confirmation. Error in calling an inorganic murmur organic is readily made unless the secondary sounds are carefully sought for. The intention of the paper was not to undervalue the importance of endocardial murmur, but to insist that it is only by the complexus of signs and symptoms that an accurate diagnosis can be made.

R. H. Babcock, M.D., of Chicago, read a paper entitled

A REPORT OF A CASE ILLUSTRATING THE VALUE OF SECONDARY PHYSICAL SIGNS IN THE DIAGNOSIS OF CARDIAC DISEASES.

Murmurs are the least reliable signs of valvular disease. An accurate diagnosis cannot be made unless the secondary signs of valvular disease are recognized. If the heart actions are not sufficiently strong, there may not be any murmur; or a grave defect may not be observed for the same reasons. Secondary symptoms are: a modified pulse-rate, character, and rhythm, leading to a congestion of the veins and internal organs. In some instances there is also systolic venous pulsation of the liver. Such systolic jugular pulsation is diagnostic of insufficiency, even if the murmur is not audible.

I. N. Love, M.D., of St. Louis, read a paper entitled

WATER.

Drugs, drugs, drugs seemed to be the chief inspiration in the life-work of too many men. Hydropathy has been a wonderful service to humanity. We can appreciate the necessity of water when we remember that seventy-five per cent. of our body is made up of water. Water is just as important as the solids in life's conditions. The de-

mands for water are affected by the amount of muscular exercise and degree of temperature to which the body is exposed. For an irritated stomach or bilious colic nothing is superior to liberal quantities of hot water. For "a night out" two or three cups of hot water, along with a cup or two of hot coffee, nothing is superior. It soothes the nervous system if you will abstain from food a few hours. Water, taken freely, acts as a purifier of the system, by flushing, and by its solvent action. The majority of people drink too little water. He would highly advise training children to drink more water. It is a most important agent in improving the complexion. Medicine should be given in large quantities of water. In typhoid fever he insists upon free drinking of pure water. No solvent will act better in removing uric acid from the system, and the only pure water is distilled water.. Copious draughts of water for its stimulating effect or the reduction of temperature, have been used many years. The hot pack in convulsions of children is often misused. Better begin with a tepid heat and add cold water gradually. Hot water locally in inflammatory conditions is most excellent.

DR. MANLEY of New York, in cystitis, knew of nothing that would take the place of water. He has often thought the surgeon's knife might be laid aside if we knew how to use water. A large number of the cases of appendicitis might be relieved by a thorough washing out of the bowel.

DR. HUGHES of St. Louis, is opposed to limiting the amount of water used at and during the meal-time. Its action is not only eliminative, but stimulating to both kidneys and bowels.

DR. STUCKEY of Louisville, could not see how water would increase or aid in the digestive function in the stomach, but its importance after digestion cannot be overrated.

DR. BABCOCK of Chicago, thought that a sufficient quantity of water might prevent Bright's disease. If the bowels be constipated and the skin dry, increased work is thrown upon the kidney. Professional men, men of sedentary habits, and women, will often escape the severity of Bright's disease by the unlimited use of water.

DR. HENDERSON of St. Paul, wished to ask the author whether or not the taking of large quantities of water will increase the fat formation.

DR. TURCK of Chicago, said the condition of the stomach must be known before the ingestion of large quantities of water was advised. The habit of taking great quantities of water into the stomach, even two hours after a meal, will hinder the process of digestion. On the other hand, if there is an accumulation of material on the walls and other viscera, then the taking of water would not be objectionable.

ISAAC A. ABT, M.D., of Chicago, read a paper on

THE CLINICAL SIGNIFICANCE OF THE CHILD'S FONTANELLE.

In health the fontanelle does not sink below or rise above its boney frame. It has both respiratory and pulsatory movements. With increased intracranial pressure the normal bruit may quite disappear. An early ossification interferes with brain development and produces a brachycephalic skull. In rachitis the involution of the fontanelle is delayed. Marked bulging is caused by the collection of fluid within. The abnormal retraction of the fontanelle always indicates a condition of inanition. If chronic, it is a serious condition. A deeply sunken fontanelle is always a danger signal in any case. Involution occurs normally at from fifteen to eighteen months. Protuberance and tension indicate meningitis.

EDUARD BOECKMANN, M.D., of St. Paul, read a paper on

OPERATIVE TREATMENT OF PTERYGIUM.

He suggested the following operation: A crescentic piece is cut from the pterygium, about five lines from its head. This part is curetted thoroughly down to the sclerotic. The head of the pterygium is dissected off. At the convexity of the piece cut out a stitch is inserted, and the opposing edges drawn together. This leaves the curetted portion to granulate and form a cicatrix. The author thinks the results from this method superior to that of any other in his experience.

WM. H. WILDER. M.D., of Chicago, read a paper on

SUBCONJUNCTIVAL INJECTION IN THE TREATMENT OF CERTAIN DISEASES OF THE EYE.

The method consists in the injection beneath the conjunctiva of minute quantities of bichlorid of mercury or cyanid of mercury in solution. The operation is not especially painful unless there be inflammation present. It has been impossible to get the same good results from the salt injections that can be obtained from the mercury.

W. S. CALDWELL, M.D., of Freeport, Ill., read a paper on

ETHER AND CHLOROFORM.

He gave an extended résumé of the statistics of death from chloroform and ether. He prefers chloroform.

C. B. PARKER. M.D., of Cleveland, O., read a paper on

THE USE OF OXYGEN IN CHLOROFORM NARCOSIS.

Oxygen and chloroform form a mechanical mixture like air. The oxygen must be perfectly pure. The time required to anesthetize is slightly longer than with chloroform, but the advantages far outweigh this minor inconvenience. There is total absence of vomiting, as well as of the extreme pallor and weakened heart beats, with shallow respiration. The duration of the shock from anesthesia is very much shorter. The patient always recovers promptly without any delirium.

W. F. BARCLAY, M.D., of Pittsburg, read a paper on

DISEASES OF THE NOSE AND THROAT IN CHILDREN.

He demonstrated that almost, if not all, of the pathological conditions, in the nose, occurring in later life, have their origin in this condition in childhood. Children should be taught to breathe through the nose rather than the mouth. Parents should be taught that surgery can relieve, very easily, those who are unable to breathe through the nose.

DR. LOVE called attention to the necessity of watching

over the child from earliest infancy and in teaching it to care for its nose. Many infectious diseases, no doubt, have their port of entry through this organ.

Dr. Coulter is convinced that there must be some other reason in producing deflective septum than the bumps that a baby received in infancy.

J. Merrill Ricketts, M.D., of Cincinnati, read a paper entitled

SURGICAL MÉLANGE.

1. Ligation of brachial artery.—Secondary hemorrhage occurred six days after an accident. Five days later another severe hemorrhage occurred. The middle brachial artery was ligated at that time. Six days later a third hemorrhage occurred. Erysipelas followed and recovery was uninterrupted. The superior profunda and its branches were the source of the hemorrhage after the ligature of the brachial. The ligatures should have been applied above the superior profunda.

2. Gunshot wound dividing the facial artery.—Roller compresses were sufficient to control the hemorrhage. Multiple abscesses appeared on the cheek subsequently, one of which left a salivary fistula. This fistula was finally closed by the introduction of a silver wire.

3. Talipes equinus varus of left foot, with external deformity.—Phelp's operation had been made one year previously, with but slight improvement. The astragalus was removed, five weeks later, through the dorsum of the foot. Division of the tendo Achillis was not necessary.

4. Hypertrophied prostate.—On the twenty-fifth day of a severe attack, double orchidectomy was performed under cocain anesthesia. He has found cocain will answer every purpose in these cases. This was the third case in which the same operation had been done. All were successful.

5. Sarcoma of the sacrum.—There was present a syphilitic diathesis. It had been previously diagnosed as a fatty tumor. Complete removal was followed by a prompt recovery, leaving a fistula from the rectum into the cavity. This was successfully closed by a later operation.

THE NEWER REMEDIES IN OTOLOGY, AND THEIR RESULTS.

Dr. Thos. Hunt Stuckey of Louisville, was elected president; Dr. H. W. Loeb of St. Louis, secretary, and Dr. W. N. Wishard, Indianapolis, treasurer.

The next place of meeting was appointed at Louisville, Ky., the third Tuesday of September, 1897.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held at Hot Springs, Va., September 8, 1896.

(Concluded.)

In continuing his paper on the subject "What Effect do Diet and Alcohol have Upon the Causation and Course of the Eczematous Affections and Psoriasis," Dr. White said he did not regard alcohol as an important factor in the causation of eczema, but there is a direct and indirect influence in keeping up the disease. Diet and alcohol have no influence upon the causation and course of psoriasis in general. In exceptional types, they have a temporary importance. It has been claimed by some that the disease can be cured by vegetable diet, while others assert that a purely animal diet is required. Both opinions have been supported by series of cases.

Definite and positive knowledge of the real nature of eczema and psoriasis, has yet to be determined by unbiased observation. Successful treatment must remain largely a matter of empirical experimentation.

Dr. Fordyce thought that we did not have definite proof of the influence of diet and alcohol upon either eczema or psoriasis. In infancy, the tendency to eczema is due largely to the delicacy of the skin. In the early stage of psoriasis, its development may be influenced by alcohol and, perhaps, also by food. In the decline, it can be influenced by almost any drug or any food.

Dr. Jackson had always thought that alcohol aggravated eczema and psoriasis. The patient should be considered apart from his skin disease. The more simple the diet, the sooner would we effect a cure. He had been unable to observe any great difference in patients treated by exclusive forms of diet. It seemed to him the simplicity of the diet was of prime importance.

Dr. Duhring said there was a vast difference between food as a cause of disease and food as an injurious factor in disease. He questioned whether food could be regarded as a cause of eczema, but that it possessed, in many instances, a direct injurious influence upon the disease he had no doubt. He thought our knowledge of eczema more clearly defined than it had been for twenty years. Where eczema and psoriasis are associated, it is an arbitrary occurrence. Certain foods appeared to aggravate eczema which already exists, more so than psoriasis. He referred to a case of psoriasis which confined the man to bed for two years. He tried first exclusive meat diet, and then exclusive vegetable diet, but without avail. An ocean voyage cured the case.

Alcohol was a less potent factor than food. It does not exert much influence in the causation of these diseases.

Dr. Dyer said that in careful investigation of infantile eczema, he found the dietary usually at fault, and proper regulation of the latter might cure while indifferent local treatment was employed. Food probably acted as an etiological factor by causing intestinal fermentation.

Dr. Morrow agreed with Dr. White that food had little effect in the causation. Psoriasis and eczema are

frequent among people whose diet is almost exclusively vegetable, as in Honolulu. Many children with eczema suffer from malassimilation, the food lacking in the proper elements for nutrition. By correction of diet errors, the eczema is improved. Private patients do much better than dispensary cases, because the dietary can be better regulated.

Alcohol has the same injurious action in eczema as in syphilis. Alcoholics suffer from severer types of these diseases. In hospital practice, psoriasis lesions can be removed by proper local treatment, but if the patient went upon a spree when discharged, the eruption would promptly return. Alcohol surely favors relapses.

DR. ALLEN said that in his hospital experience, psoriasis occurred largely among alcoholics, and the manifestations quickly recurred in an aggravated form if alcohol was indulged in. He thought its influence greater than that of food. The converse of this could be considered true for eczema, excepting certain infantile forms. In his dispensary experience, children allowed a mixed and faulty diet, often including beer, tea, and coffee, were apt to develop eczema, and once developed it was aggravated by such diet.

DR. ROBINSON said the molecular constitution of our protoplasm depended upon the kind of food we took. This has been demonstrated in the laboratory. If psoriasis and eczema are regarded as parasitic diseases, and if we admit that organisms require a special soil for their growth, the question arises whether alcohol tends to furnish such a favorable soil. In indigestion, particularly that of fermentation, certain toxins are formed, and from them a toxic eczema might become established. Sugars he had found especially injurious, particularly in children permitted to eat cheap candies. If the diet is regulated and a mild application, such as one containing boric acid, is made, the eczema quickly disappears.

DR. WHITE had stated that there was no demonstration of a direct connection between gout and rheumatism, and psoriasis and eczema. He thought it would be admitted that gouty subjects were pretty sure to have, sooner or later, an interstitial nephritis. Urate of soda has been found upon the skin in cases of gout. Internal treatment directed to the gout may cure an eczema which otherwise will not respond to remedies. In psoriasis, food did not have much influence because its action could be counteracted by internal medication. He relied upon an alkaline condition of the system, and arsenic for a more or less specific effect. Much less alkaline medication was required if the diet was properly regulated. He had seen recovery on exclusive milk and vichy. Indulgence in spirits would determine a relapse. Perhaps the alcohol only made the ground favorable for microörganisms. He said, in closing, that the president's remarks were based on the supposition that we here had a parasitic disease to deal with, while we have no positive knowledge that such is the case. Eczema occurred most frequently in the first year of life when the food was the simplest and most uniform. As the food became complex the frequency decreased. Personally, he did not employ internal treatment in infantile eczema.

DR. DUHRING supplemented his remarks by saying that food influences the nutrition of the skin in eczema in a notable degree, and hence, must be regarded as an important factor in the history of eczema.

The next paper was by J. T. BOWEN, M.D., of Boston, on

MYCOSIS FUNGOIDES AND SARCOMATOSIS.

The paper described cases which illustrated the difficulty which one sometimes encounters in separating these two types of cutaneous affection. A study of cases reported previously, along with those now described, lends weight to the opinion that there are transitional forms between the two affections, as has been already suggested by Kaposi.

DR. WHITE thought we must regard the fugitive character of these lesions as common to both mycosis and sarcoma; certainly the many hundreds of nodules in multiple sarcoma, which disappear in a few weeks, in some instances, under arsenic, are as fugitive as if they disappeared without treatment. The size of lesion is only a matter of degree.

DR. DUHRING had seen many cases of what Dr. Bowen called "mycosis fungoides," but he objected to the name, preferring granuloma fungoides.

DR. FORDYCE said there was nothing very distinctive in the pathological anatomy of mycosis fungoides and certain forms of sarcomatosis. It was well known that there were types of spindle-cell sarcoma, which could be differentiated by the microscope, but mycosis fungoides of the Kaposi type and certain other forms could not be well distinguished, and it was not at all probable that some of these had different origins not yet understood.

In the session devoted to the exhibition of drawings and photographs of rare cases, J. A. FORDYCE, M.D., of New York, showed two water-color sketches of an unusual form of

IODOFORM DERMATITIS

occurring in a man with pulmonary tuberculosis, following the application of the drug to a contused wound of the finger. The eruption consisted of large patches of grouped tubercles, papules, papulo-vesicles, pustules, and elevated erythematous spots involving the hands, forearms, neck, and face. A colored drawing showing almost identical lesions from the internal use of iodid of potassium was also shown.

MULTIPLE PAPILLOMATOUS TUMORS

were illustrated by several colored drawings.

DR. WHITE said that in a series of cases of iodoform poisoning he had failed to observe the appearances shown in Dr. Fordyce's drawing.

DR. DUHRING complimented Dr. Fordyce on the skill shown in his microphotographic work.

DR. MORROW had seen bullous lesions from the topical application of iodoform. Lesions on the face were probably due to local transfer from the point of application, rather than from systemic effect.

DR. ALLEN said he had observed appearances quite similar to those depicted, also from the application of iodoform to a crushed finger. He had seen a number of

severe iodoform eruptions following application of the drug to crushed members, so that he had come to believe there might be a peculiar connection between such injuries and the occurrence of the dermatitis. In some instances he thought lesions at a distance depended upon absorption of the toxic drug.

Dr. Fordyce thought the presence of tuberculosis accounted for the severity of the symptoms. He had twice seen the application of iodoform to a crushed finger produce a bullous eruption on the face, arms, scrotum, and legs.

Dr. Morrow presented colored photographs of the

PRE-MYCOTIC STAGE OF MYCOSIS FUNGOIDES.

The case had been under observation for two years. The eruption was always of the urticarial type, but had undergone marked changes. As erythematous spots, enlarged by peripheric extension, and disappeared, new ones would take their place. Treatment by the toxins of erysipelas had aggravated the condition.

Dr. Duhring considered the salmon color rather characteristic of granuloma fungoides. Dr. White spoke of a case showing brown patches, which had been sent to the hospital with the diagnosis leprosy.

Dr. Dyer of New Orleans, presented photographs of unusual conditions in the negro, such as leprosy; the marked tendency of scars to develop into keloid; tinea circinata; alopecia areata, the only instance he had ever seen in one of this race; an unusual type of leukemia in a young girl, etc.

A. R. Robinson, M.D., of New York, presented the next paper upon

XANTHOMA DIABETICORUM.

The patient whose case was described, and of whose eruption colored photographs were shown, was a woman who had her first attack in 1891. The eruption at this time appeared upon the anterior surfaces of both forearms and upon the elbows, with a few lesions upon the knees. All disappeared excepting those upon the elbows, and remained away for several months.

In the attack now described, about 150 lesions occupy space between the wrist and midway between the elbow- and shoulder-joints. They are from pin-point to pin-head size, elevated, light yellow, with faint tinge of red. Pressure develops yellow tinge, but the red returns on its removal. Grouping is well marked in spots. Over the elbow is a patch 1½ inches in diameter composed of about fourteen small groups. No lesions on palms. Upon legs, about fifty lesions on each side, extending from middle of the thigh to below the knee. No lesions on eyelids or other part of face. No history of diabetes in the family. The urine is strongly acid, has a specific gravity of 1023, and contains twenty per cent., by bulk, of albumin. Sugar test is negative, but urine is said, by the chemist, to be of "glycosuric nature."

In the discussion, Dr. Duhring said a case with similar lesions, so small as to render diagnosis difficult, had recently been seen by him. Under antidiabetic treatment the papules disappeared, but returned when ordinary diet was resumed.

Dr. Morrow said that sugar was not always present in these cases. He cited Besnier's case, which had been observed for several months without sugar being discovered. In another instance sugar was found only after breakfast.

Dr. Fordyce had seen a similar case in Dr. Elliot's clinic.

Dr. Allen thought sugar would be found in Dr. Robinson's case in time. He had seen intermittent glycosuria without skin eruptions.

Dr. Morrow said it was well known that diabetics frequently develop interstitial nephritis, and if the sugar has previously disappeared it is apt to return at such time.

C. W. Allen, M.D., of New York, read upon

SOME GLYCOSURIC DERMATOSES.

If the dermatoses, which have been called by the French *diabétides*, were in the main pathognomonic of the underlying condition which their presence suggests, the term might well take its place along with the syphilides, scrofulides, tuberculides, and leprides. The chief objection which the writer offers to this is that the eruptions occur in the presence of the symptom of glycosuria, which is not to be confounded with the disease diabetes, and hence the term is a misnomer. A number of instances were related in which skin eruptions occurred coincidentally with sugar in the urine, and some which disappeared when the urine became sugar-free. In one case multiple gangrene, extending over limited areas of the skin surface, had been observed. The patient had undergone several such attacks at times when the percentage of sugar was notably high. A peculiar bronzing of the skin had occurred upon the surrounding areas affected, and a marked hairy growth had taken place in a number of these pigmented spots. In one case the lesions had closely simulated those of acne varioloformis of Hebra, but had occurred in other regions than those usually occupied by the latter disease.

While glycosuria is a symptom of a variety of different conditions, originating in different organs of the body, and still far from being understood, it is attended with a series of cutaneous manifestations which are at times almost enough in themselves to warrant a diagnosis of the presence of sugar. We know as yet of but few cutaneous manifestations which are so pathognomonic or peculiar to diabetes as to warrant us in making of them a class by themselves.

DISCUSSION.

Dr. White said that a furuncular diathesis was not a necessity, since the skin in these cases furnished a good nidus for the development of furunculous coccus. The reader had failed to mention the very acute eczema of the genital regions in stout diabetic women. He had often noted an intensely acute form of erythematous eczema or dermatitis, which possessed a very evanescent character. He came to look upon this dermatitis as characteristic of diabetes.

Dr. Morrow said these eruptions had been explained on the assumption that they were due to the local contact of saccharine urine and the products of its decomposition affording the development of certain fungi and parasitic

growths. This would not explain eruptive troubles upon the distant parts. The presence of sugar in the blood modifies its power of maintaining the nutrition of the tissues. He found many of the eruptions could be explained in the same way as drug eruptions—by the presence of a foreign substance in the blood.

I. DYER, M.D., of New Orleans, reported an interesting case of

HYPERTROPHIC ROSACEA (PACHYDERMATOSIS) RESEMBLING TUBERCULAR LEPROSY, CURED WITH THYROID EXTRACT.

Many of the symptoms resembled those of leprosy, which is so prevalent in that part of the country in which the case occurred. The patient was a farmer, sixty years of age, giving scant family history, and complaining but little of the itching and annoyance of the eruption, but seeking relief more for the cosmetic effect. There was marked infitration of the face and back of the hands, to which regions eruption was limited. The patient's general health was, and had always been, good. A photograph was presented, showing the great thickening of the skin in rugæ, running for the most part in parallel lines, a pencil's breadth apart, crossing each other at points one-half inch distant, more or less, from each other. There was much itching, and extensive scaling. The color was red rather than brownish or bronzed, as one would expect to find in tubercular leprosy. Then, too, there were no tubercles nor telangecteses. Various forms of treatment were tried without beneficial results. The diagnosis was suggested by a picture in the "Atlas of the St. Louis Hospital Museum of Paris," which appeared to be a counterpart of the writer's case. Thyroid extract tablets, five grains each, were given three times a day, and continued over several months, with some intervals. Under this treatment the skin became soft and normal to the touch, and in general appearance. The photographs presented showed a marked change in the patient's appearance after treatment.

No longer could confusion with tubercular leprosy be made. Besides the other points, which would exclude leprosy, were the limitation to the exposed regions, the absence of trophic changes, and the total absence of true tubercles.

In discussing Dr. Dyer's paper, Dr. White said that the appearance presented in the photographs and from the description did not recall to his mind any case of ordinary pachydermia which he had seen. He asked if there were other evidences of myxedema present than those suggested by the photograph.

DR. DUHRING could not accept the diagnosis of hypertrophic rosacea, while the term pachydermatosis seemed to him quite appropriate. Dr. Jackson favored the diagnosis of mild myxedema, in which view Dr. Fordyce concurred. In closing, Dr. Dyer said that there had been no evidence to warrant a diagnosis of myxedema. He had changed his designation to hypertrophic rosacea, after seeing the plate so entitled in the "Atlas of the St. Louis Museum Collection of Wax Models." There had been no evidences of cellular edema. The hypertrophy had developed gradually and had lasted for nineteen years. There was no enlargement of the thyroid gland.

THE RELATION OF DERMATITIS HERPETIFORMIS TO ERYTHEMA MULTIFORME AND PEMPHIGUS,

was the paper next presented by DR. DUHRING, who concluded (1) that dermatitis herpetiformis was, in most instances, a disease with well-defined, tolerably constant clinical features; (2) that, in most instances, it was more closely allied in nature to erythema multiforme than to any other disease; (3) that the bullous variety of dermatitis herpetiformis possessed features that resembled those of pemphigus vulgaris, from which latter disease, however, it differed in the peculiar inflammatory and herpetiform character of the cutaneous lesions, as well as in the tendency to polymorphism, the irregular evolution of the lesions, and in its course.

DR. FORDYCE thought all dermatologists in this country recognized the existence of dermatitis herpetiformis. In a case recently seen with multiform lesions, bullæ, and pigmentation, a chronic nephritis was present, which he thought was the cause, by keeping certain chemical products in the system, of the irritation of the skin.

DR. ROBINSON thought it an unfortunate use of the term dermatitis. When multiformis was added to it, it had no meaning at all. He therefore preferred "herpetiformis." The neurotic nature had not been accepted. He regarded it as a toxic manifestation through the vascular system, or perhaps the nervous system.

Dr. J. C. White of Boston was chosen president, Dr. L. A. Duhring of Philadelphia, vice-president, and Dr. J. T. Bowen of Boston, secretary and treasurer.

REVIEWS.

WHITAKER'S ANATOMICAL MODEL: A Pictorial Representation of the Human Form and its Organs, with descriptive text. By DR. SCHMIDT. Thomas Whitaker, publisher, Bible House, New York.

THIS is an attempt to give the reader a pictorial representation of the human body and its organs by superimposed pictures, giving the appearance of the human body as it appears in sections made at various levels. The book is one of a series edited by William S. Furneaux.

ANATOMY OF THE HUMAN HEAD AND NECK is another volume in the same series. They are valuable for school-children who are studying physiology, and may be of service also in training-schools for nurses.

REFERENCE AND TEXT-BOOK. By C. HENRI LEONARD. Fortieth thousand. Illustrated Medical Journal Co., publishers, Detroit.

THIS is a new and enlarged edition of the *multum in parvo* reference- and dose-book. It is printed on very thin paper, bound in red leather, flexible covers, round corners, adapted for the pocket. Besides giving the doses of over three thousand preparations, it has numerous tables.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, OCTOBER 10, 1896. NO. 15.

ORIGINAL ARTICLES.

DISEASE OF THE ACCESSORY CAVITIES OF THE NOSE.[1]

By GEO. M. PEAVLER, M.D.,
OF BRISTOL, TENN.

IT is only in very recent times that much attention has been given to disease of the accessory cavities. This seems a little remarkable when we consider that this is the most serious of all nasal disorders, is of very common occurrence, and presents symptoms that are very pronounced, very annoying to the patient, and easily recognized by the physician. The accessory sinuses, four in number on either side, are the maxillary, the frontal, the ethmoidal, and the sphenoidal. These communicate with the nasal cavities proper, through small openings which allow of an interchange of air during health, and through which pus is discharged into the nasal chambers during disease of these sinuses. We believe that these cavities have no very important physiological function. While they are known to serve as reservoirs for warm air, and in this way contribute a little warmth and moisture to the air taken into the lungs, yet the air emptied from these cavities is so small in amount, compared with the volume of air taken in at each inspiration, that it must be considered as insignificant physiologically. We think the real design of these cavities was to afford lightness to the bones of the face without compromising their strength or symmetry.

Any of these cavities may become diseased, which is usually made known by a purulent discharge from the nose, more or less offensive in character, and which does not yield to ordinary treatment. Such chronic discharges never come from the mucous membrane of the nasal fossa, for the ordinary forms of chronic rhinitis are not accompanied by a purulent discharge; and when pus is found coming from the nasal cavities it may be accepted as conclusive evidence of diseased bone; and, on inspection, it will nearly always be found that the pus is running from one of the accessory sinuses. The matter discharged from the diseased sinus may vary in its consistency, and odor, as well as in the frequency of the discharge.

An analysis of the cases occurring in our practice for the past five years shows the total number of patients suffering from disease of the accessory cavities to be thirty-five. Of these thirty-five cases there were twenty-four cases of disease of the antrum of Highmore, ten cases of ethmoid disease, and one case of disease of the sphenoid cells. After having seen several cases of chronic empyema we were led to observe that, in the majority of the cases where the disease was of long duration, mucous polypi were found in the nose. We readily concluded that this was not accidental; but that the empyema stood in a causative relation to the intranasal tumors. Extended observation has greatly strengthened us in this belief. For out of a total of thirty-five cases of empyema polypi were present in twelve, or about thirty-four per cent. of the whole number. Eliminating from the calculation cases of less than one year's standing, and basing our estimate on the chronic cases alone, we find mucous polypi to have been present in about sixty-three per cent. of such cases. It would appear that polypi are most likely to be found where disease has existed for some time; and that they are found associated with disease of the ethmoid cells more frequently than elsewhere. Of the ten cases of ethmoid disease polypoid growths were present in seven. Grünwald has recorded seventy cases of accessory sinus disease. Of these seventy cases polypi were present in thirty-three, or forty-seven per cent. As his cases were all grouped together we have reason to believe that the percentage would have been much higher had the cases of recent standing been excluded from the calculation. Hence we reach this practical conclusion: That in quite a large percentage of the cases where polypi are found they are the result of chronic suppuration; and that the presence of such growths should always lead one to suspect that there is diseased bone, and hence calls for an inspection of the accessory sinuses. The antrum of Highmore, and the ethmoid cells, furnish by far the greatest number of empyemas.

As to the etiology of antrum disease we shall say only a few words. That carious teeth are often the primary cause of pus in the antrum we have no reason to doubt; and this important fact must not be lost sight of in studying the etiology of a case. Quite a large proportion of the cases

[1] Read before the Tennessee State Medical Society, April, 1896.

of empyema owe their existence to an abnormal or disordered condition of the nasal cavities. Many patients date the beginning of their ailments from the taking of a severe cold or the grip. During the stage of active inflammation there is an excessive outflow of mucus or mucopus into the antral cavity; and the swelling of the mucous tissue around the orifice, together with the swelling of the turbinated tissues in the nose, causes a retention of these inflammatory products, and thereby results the condition of empyema, which becomes chronic and persistent. Stenosis of the nasal cavity, by whatever cause produced, is liable to be followed by disease of the antrum. Hence nasal tumors, hypertrophic rhinitis, foreign bodies, and traumatisms, may all indirectly lead to antral disease by closing the hiatus, causing the retention of decomposing secretions. Deflection of the nasal septum, which makes one respiratory chamber unusually large at the expense of closing the other, can in the same way lead to antral disease on the side of the closed nostril.

The symptoms observed in the course of this disease are not always sufficient to establish a diagnosis beyond a question of doubt. In most cases, however, the symptoms are marked, and the evidences of disease are unmistakable. There is in some cases a sense of pain about the cheek, radiating pains about the eye, and pain or soreness in the teeth, when pressure is made over the canine fossa. When there is a closure of the hiatus and a retention of the secretions, there is apt to be distention, extreme tenderness, and a bulging upward of the floor of the orbit, causing exophthalmos and double vision. The discharge from the nose is a very annoying symptom, necessitating the frequent use of the handkerchief. The pus is generally thick like cream, and often has a fetid disagreeable odor. This incessant filthy discharge is the most unpleasant of all the symptoms, and is the one which usually drives the patient to seek relief. If firm and equal pressure be made over the two antra, one healthy and the other diseased, a difference in sensation is experienced by the patient; the comparison shows a tenderness on the diseased side; the obtuse sensation lasting for a time after the pressure has been removed. This is a diagnostic point on which I have learned to place a good deal of reliance; and a careful rhinoscopic examination will be likely to reveal a discharge of pus, creamy in color and consistency, running from the region of the middle meatus. This pus when wiped away will sometimes quickly reappear at the same point, and can thus be seen trickling down from the natural opening. By a bending forward of the head the flow of pus from the antrum will be accelerated; a fact to which attention was called by Boyer. It should not be forgotten that the infundibulum has its opening in the middle meatus, not far from the antral opening; and hence a purulent discharge from the frontal sinus would show itself in nearly the same locality as one from the antrum of Highmore.

In our endeavors to obtain facts from which we can make a correct diagnosis we may often adopt the following procedure with good results. The nasal cavity is thoroughly cleansed of all secretions, a four per cent. solution of cocain is then applied for the twofold purpose of shrinking the tissues and producing local anesthesia. We take a syringe holding about two drams. To this there is fitted a long narrow cannula which is bent at a right angle, near the distal end. The syringe is filled with fluid, the cannula introduced into the nose, and the bent point slipped along the middle meatus until it drops into the antral opening. The fluid is then injected into the antrum, and if pus is present it can be seen to pour out from the ostium maxillare as the fluid enters. The pus thus discharged usually has a foamy appearance, owing to its sudden mingling with the fluid injected. Deviations of the septum and other hypertrophic changes will occasionally hinder us in making this test.

Where any uncertainty exists we may open the antrum. The perforation can be made through the nose by penetrating the outer wall through the inferior or middle meatus, or through the alveolar process after the removal of a tooth, or preferably in the canine fossa. In this way we are able to find the pus if there be any, and having found it, we already have an opening through which we can proceed to medicate the diseased cavity.

Opening of the antrum from the nasal fossa does not afford thorough drainage, for the reason that the floor of the antrum is lower than that of the nose. The opening presents difficulties in keeping it from closing and is not convenient of access. The most serious objection to boring upward through the alveolar process is that a tooth must nearly always be sacrificed in the procedure. Again, the wound has to be plugged to prevent food from entering the cavity; and by closing the hole with a plug we have, in a degree, thwarted the purpose for which the operation was done. I prefer to enter the cavity at a point a little above and between the roots of the second bi-

cuspid and first molar teeth. If the first molar is out we prefer to enter directly above, or through the lower portion of the malar ridge. A pledget of cotton, saturated with a ten per cent. solution of cocain, is placed on the spot selected for the operation. After a few minutes the cotton is removed, and a few drops of a four per cent. solution is injected into the submucous tissue; a small amount of the solution should be injected beneath the periosteum, which can always be done by a proper manipulation of the needle. In ten minutes the local anesthesia is completed to an extent that the perforation can be made almost without pain. The drill, or trephine, whether run by an electric motor or by hand, is passed in a direction upward, backward, and inward, making an opening of sufficient size for the easy irrigation and medication of the diseased cavity.

After the opening has been made the important question arises as to how it shall be kept open; and by what means the diseased cavity is to be irrigated. The old method of fastening the tube into the opening by wiring it to the teeth was bunglesome and unsatisfactory. We have devised a means of treating these antrum troubles, which offers some advantages over other methods, and is, at the same time, free from some of their disagreeable features. We use a tube which is self-retaining, and can be worn for months without discomfort or inconvenience to the patient. The irrigation is done by the patient himself, and as many times a day as is thought necessary. The opening in the antral wall is made by a drill of definite size, about five millimeters in diameter. The tube is made of a size to fit exactly the opening made by the drill, and is slightly swollen on the distal end so as to make it self-retaining. To prevent it going too far into the cavity, as well as to prevent the end projecting into the buccal cavity from becoming covered over with mucous membrane, this extremity of the tube is provided with a head or smooth rim. This end of the tube is also sloped so as to make it lie smoothly against this slanting bone-surface through which it passes. The tube is made of silver, and is five-eighths of an inch in length. It is introduced by means of a pilot. The tube being in position the patient takes fluid into his mouth, and by a pumping motion of the cheeks causes it to pass rapidly into the antrum, and thence by the natural opening into the nose. In this way several ounces of fluid can be passed through the cavity in a few minutes. The patient should be ordered to do this several times a day.

The irrigation in the chronic cases has usually to be kept up through a long period, in some instances for a year or two. Where the case progresses unfavorably, the symptoms showing no sign of abatement, it will be found best to enlarge the opening to an extent that the cavity can be carefully explored. If polypi are found they should be removed; membranous partitions should be broken down if present, and dead bone surfaces carefully curetted. When the mucous membrane is much thickened, and covered with fungosities, and flabby granulations, due to long-continued suppuration, it should be curetted carefully throughout the whole cavity.

The treatment of ethmoid disease is mainly surgical. The aim is to reach the diseased cavities and effect their free drainage, as well as a removal of the carious bone. There are two pathological conditions, either of which may hinder our approach to the seat of trouble. It is quite usual in these cases to find hypertrophy of the middle turbinated body sufficient to conceal all view of the parts beyond it. It is no less common, especially in the chronic cases, to find the nose blocked with mucous polypi. In either case the first thing to do is to remove the hypertrophic conditions, and thus effect an unobstructed entrance to the diseased sinuses. By careful inspection and use of the probe we can usually locate the source of the discharge. In operating on these cells our aim should be to do thorough work, remembering at the same time the delicate structures that surround the field of operation. In front and toward the medium line we have the cribriform plate and olfactory nerves. To the outer side is the infundibulum, and a frail bone tissue, which separates the cells from the orbit. In doing these operations we should take our bearings carefully and proceed cautiously. The curette is the instrument best suited for removing the diseased tissue. Forceps are likewise useful, and, as a supplement to the curette, afford a safe means of removing the carious bone. With these instruments we can, as it were, feel our way, and by this tactile sense we are able to discriminate between healthy and diseased structures. A rough or grating sensation will indicate that the probe is in contact with carious bone. Thorough removal of all diseased tissue is the end to be sought, and to accomplish this we may have to repeat our operations from time to time, as the work is not likely to be completed at one sitting, especially if done under local anesthesia.

In addition to the surgical treatment the nasal fossa must be kept clean. The foul accumula-

tions should be washed away by frequent irrigation with some mild antiseptic solution. This will add greatly to the patient's comfort and be of material aid to the surgical treatment.

THE TREATMENT OF SYPHILIS BY MEANS OF THE TOXINS OF ERYSIPELAS AND THE BACILLUS PRODIGIOSUS.

By ROBERT H. GREENE, A.M., M.D.,
OF NEW YORK;
ATTENDING PHYSICIAN TO THE CITY HOSPITAL.

CASES have been reported by Mauriac[1] and Rudolph[2] of individuals who, while suffering from the cutaneous manifestations of syphilis, have been attacked by erysipelas, the result being the disappearance of the syphilitic eruption from the skin. The perusal of this literature as well as of the articles of Coley[3] on the treatment of sarcoma by means of the toxins of erysipelas and *Bacillus prodigiosus*, led the writer to experiment with these toxins in the treatment of syphilis. While the number of cases experimented upon, the histories of which are recorded below, are insufficient data from which to draw a positive conclusion, the tentative conclusions arrived at by the author are as follows:

(1) These toxins can be administered hypodermically in proper doses, with no danger of the formation of an abscess at the point of the injection, and with practically no danger of any serious constitutional reaction following their administration. (2) That in almost every case changes in the appearance of the cutaneous manifestations of syphilis macroscopically can be plainly observed in from forty-eight to seventy-two hours after the commencement of the injections. (3) That it is apparently at the present time extremely difficult to procure solutions containing these toxins of any uniformity of strength, one preparation producing rapid changes, another slight changes. It is to be regretted that in taking clinical notes of the cases, the proper record concerning the administration of the different supplies of the toxins was not kept, the necessity for this record not being as apparent when the investigations were first begun as developed later. (4) The reappearance of the cutaneous eruption in two cases would tend to show that we must not conclude from the simple disappearance of the cutaneous manifestations, that any permanent change has taken place in the course of the disease. When erysipelas itself apparently caused the resolution of the cutaneous manifestations, as reported in the histories of the cases of Mauriac and Rudolph, fresh eruptions appeared later on.

It was found extremely difficult to keep these patients under observation as long as was desirable, from the fact that they were not confined in hospitals, that they principally belonged to the floating population of New York, and in several instances having obtained employment outside of the city, were on that account removed from observation. I wish to express my deep gratitude to Dr. Coley, who very kindly presented me with the solutions which I used in these cases, being identical with those which he had found of benefit in cases of sarcoma under his care, and also for kindly advice concerning the administration of the toxins.

I was supplied by Dr. Coley with two solutions, one that had been filtered and sterilized by the addition of an antiseptic, the other sterilized by heat and unfiltered. I used, during the latter part of my experiments, the unfiltered preparation exclusively.

CASE I.—April 9, 1896. J. M., aged twenty-nine; occupation, mason. First appearance of the initial lesion occurred July 15, 1895. This, according to his history, was followed by spots on the body five or six weeks later. Since that time he has been almost continually under treatment by means of pills, liquid medicine, and inunctions; had been in the Philadelphia Hospital for some time, and treated by divers physicians, privately and in dispensaries. Four weeks previously the present eruption appeared, while he was still taking small pills. He has pain on the top of his head, much worse at night, sleeps poorly, and his legs are weak. He has become reduced in weight from 174 to 135 pounds; has large scaling syphilid on left shoulder and on right temple, and a few large flat papules on forehead. One minim of filtered solution was administered in the left shoulder.

April 10th: Eruption commencing to fade. Complains of sleeplessness. One minim filtered solution.

April 11th: Eruption about the same; no change. One minim.

April 12th: Eruption fading; complains of general feeling of malaise. Did not administer solution.

April 14th: Feeling better; sleeping better. Administered one minim.

April 15th: Administered two minims.

NOTE made May 9th.—Have not seen patient since April 15th. At that time, eruption had entirely faded, and had been fading regularly since

[1] "Étude Clinique sur l'Influence Curative de l'Erysipèle dans la Syphilis," Paris. 1873.

[3] The indications for non-operative local treatment of tumors; the value of toxins.—W. B. Coley, M.D., N. Y. State Med. Assoc., October 16, 1895.

the commencement of the administration of the toxin.

Case II.—J. R., first seen April 16, 1896, gives history of initial lesion three months ago. At present he has a general glandular adenopathy, erythematous syphilids, a few moist papules and condylomata around anus, sore throat, pain in legs, etc. Administered two minims filtered solution.

From the 17th to the 21st, there was an increase of one minim in the administration each day. On the latter date, the pain had disappeared; glandular adenopathy diminished; condylomata and papules had almost entirely disappeared. From the 22d, when seven minims were administered, there was a daily increase of one minim until the 27th. On that date, the 28th and the 29th, twelve minims were administered. May 8th: Patient was discharged with no evidence of syphilis apparent anywhere, except that the very slightest enlargement of the inguinal glands could be felt.

On May 16th and June 7th, there was no evidence of any return.

Case III.—J. M., first seen May 2, 1896; aged thirty-four; occupation, laborer. History of initial lesion seven years ago, followed by cutaneous manifestations which persisted most of the time during three years. Never had any treatment. The present cutaneous manifestations have only recently appeared. Headache, worse at night; numerous scars; a number of large flat papular syphilids on body; scrotum covered with moist excoriations. Gave five minims of the filtered solution.

On May 4th, six minims were given; May 5th, seven (complains of headache and backache); May 6th, eight (syphilitic papules fading); May 7th, nine; May 8th, ten; May 9th, five, of the unfiltered. Papules had then almost disappeared; some headache and pain in shins; pains better than for several days; scrotum is entirely healed; only application having been of pure vaselin.

On May 10th and 11th, five minims unfiltered were administered, and from the 12th to the 16th inclusive ten minims daily were administered.

May 20th: A few flat papules have made their appearance on back of neck. Has had no headache or backache. Occasionally has pain in legs. Three days ago gums began to be sore; has slight excoriation of gum on front of left incisor. Gave ten minims of the unfiltered.

May 21st: Large flat papules, which had made their appearance on back of neck, are much dried up, and have become scaly since the day before.

May 22d: Ten minims of unfiltered solution; papules drying up.

May 28th: No indications of syphilis outside of the old scars, except the stains of the flat papules between the legs, and the papules on the neck. These are scaly, and present about the same appearance as when last seen. Gave ten minims of the unfiltered.

Note.—Patient has not been seen by me since the 28th of May.

Case IV.—P. M., aged twenty-six. May 2, 1896. Has elevated and excoriated chancre on outside of glans penis, as large in circumference as a quarter of a dollar; glandular adenopathy; erythematous syphilid; a few small miliary papules on both the anterior and posterior surfaces of the body. Injected five minims of the filtered solution.

May 3d: Surface of chancre changed in color, from bright red to pink.

May 4th: The chancre is healing. Six minims.

May 5th: Gave seven minims. Eruption has faded in a marked manner; erythema practically disappeared; papules diminishing in number; feels better.

On the 6th, 7th, and 8th, ten minims were administered daily.

May 9th: Five minims of the unfiltered. Eruption has disappeared from front of body; chancre has much less irritated appearance, and there is a slight red zone surrounding it. Patient feels very well.

On the 10th and 11th, six minims unfiltered were administered daily.

May 12th: Five minims unfiltered. Patient has a bad headache, frontal, came on at four in the afternoon of May 11th, and during the night felt chilly and had fever. At present (12 M.) no pain; has oral temperature of 99° F.; eruption apparently slightly more prominent on neck.

May 13th: Headache. Had no injection.

May 14th: Better; no injection.

May 15th: Five minims of the unfiltered (slight headache).

May 16th: Five minims of the unfiltered; chancre healing; headache at 4 P.M.

May 17th: Chancre healing in a marked degree; body clear. Omitted injection.

May 18th: Injection of two minims unfiltered.

May 19th: Two minims unfiltered; slight headache.

On May 20th, gave two minims unfiltered.

May 21st: Four minims unfiltered (complained of no headache the day before).

On the 22d, 23d, and 24th, three minims. All cutaneous evidences of syphilis have disappeared, except slight scab on chancre.

On the 25th and 26th, three minims were administered.

May 27th: Having exhausted my supply of Coley's solution, used five minims of plain erysipelas toxin.

May 28th: Gave ten minims of same solution.

May 29th: Slight headache, beginning the day before at 3.30 P.M., continuing till 10 A.M.; slight injection having been administered at 10 A.M.

June 3d: Discharged, with no evidence of syphilis, except very slightest enlargement of the inguinal glands to be felt. Ordered him to report once a week.

Note.—Patient reported for observation once

or twice during the early summer, with no indications of any return of the cutaneous manifestations. He has not been seen since.

Case V.—May 16th. W. O. B., aged twenty-three. Six years ago initial lesion on penis, sore throat, tongue, etc. Had been treated at Bellevue. One year ago had sore come out on elbow, which had been under treatment ever since by various physicians in dispensaries. The history given was that it would improve somewhat and then grow worse, but it never entirely healed since it first made its appearance. Two weeks ago, sore on the penis made its appearance. Has gumma size of a dollar, just above left elbow; has another on top of glans penis, which has eaten away the tissues to the depth of a quarter of an inch; was presented to Dr. Joseph Collins for inspection. Two minims of the unfiltered were injected.

May 17th: Patient did not appear.

May 18th: Marked change has taken place in appearance of gumma on elbow; it was dried up to a considerable extent. Gumma on penis apparently about the same. Patient states that elbow has not been so dry in a year and a half. No headache. Four minims of the unfiltered injected.

May 19th: Gumma on penis healing. Four minims of the unfiltered.

May 20th: Did not appear.

May 21st: Patient states that he has been ill with a headache, which came on the night of the 19th; the toxins were administered in the forenoon of that day; gumma on elbow much improved; patient states that it is no longer sore when he leans on it; gumma on penis previously excoriated, covered with a dry scab. Administered five minims of the unfiltered.

May 23d: Patient did not appear on the 22d; states that he had severe headache, accompanied with shooting pains, which came on about 8 P.M. on the evening of the 21st, and which lasted all night; did not have headache the night of the 22d. Administered two minims of the unfiltered. Both gummata have improved.

May 31st: Has been in the penitentiary since last seen, and has had no treatment of any kind in the interim. Gumma on penis is almost entirely healed; gumma on elbow, which had previously scabbed over, has lost its scab on the upper half, and there is a profuse gummy exudate. It is not in as good condition as when last seen. Administered ten minims of unfiltered.

June 1st: Has had severe headache and pain in bones since eight o'clock last night. Gumma on elbow has less irritated appearance. Patient states that he sleeps better than before having the treatment. Administered four minims of unfiltered.

June 3d: Has had no headache since last night. Administered three minims of the unfiltered.

From the 4th to the 6th, three minims of the unfiltered were administered daily; from the 7th to the 10th, five, when the gumma improved, filling in centrally from the edges.

Note.—September 25th. This patient has not been seen by me since June 10th. At that time, if my memory is correct, although there is no note in history book, the gumma on penis had healed. There had not apparently been as much improvement in the condition of the gumma on elbow from May 31st to June 10th, as there had been from May 16th to May 23d. Whether that may have been owing to the fact that I was using a different preparation of the solution during the second period, or whether the apparent usefulness of the injections had ceased, I am unable to state. This large gumma on the elbow was apparently healing in the same manner as the large chancre healed in Case IV, by the formation of a red zone around it on the outside showing, I presume, an increased phagocytosis. There was gradual filling in toward the center.

Case VI. — J. McC., May 20, 1896; aged twenty; occupation, laborer. Initial lesion nine months ago. Two months ago (?) phimosis. General glandular adenopathy; very extreme enlargement of the glands of the left inguinal region; large number of papular syphilids scattered generally over the body; had had no treatment; sleeps well; has headache and sore throat. Administered two minims of unfiltered.

May 21st: Administered three minims of the unfiltered. No perceptible difference to be observed; had some headache.

May 22d: Papules much faded; patient states that some have become scaly that were not so before; large glandular enlargement in left groin considerably diminished. Administered five minims of the unfiltered.

May 26th: Administered five minims unfiltered; May 27th, ten (papules much faded; swelling of foreskin improving).

May 28th and 29th, being out of solution, gave ten minims of plain erysipelas toxin. No change.

June 21st: Eruption fading slightly; patient thinks a few new papules have appeared around anus.

From June 2d to June 10th, four minims of the unfiltered were administered. Then the patient was doing well; gained five pounds in weight; no sore throat; large number of the old papules have disappeared leaving stains; inguinal glands much diminished in size; extreme enlargement of those on the left side having disappeared.

On June 11th, there were administered five minims; 12th, four; 15th, six; from the 18th to the 26th, ten minims daily.

From June 27th to July 10th, ten minims daily of new solution.

Note.—At this time, not having seen much improvement, in fact very little, if any, change, either for the better or worse since the 10th of June, I felt that it was a duty I owed to the patient to adopt some more certain method of relief, and I stopped the administration of the toxins

and put him on inunctions of mercurial ointment, and a tonic. I saw him a few times after that, during which time he had improved somewhat, and then lost track of him through my absence from the city.

Case VII.—May 26, 1896. E. A., aged twenty-three; occupation, truckman. History of initial lesion three months ago; sore throat for a month; two weeks ago spots on body. Has marked erythema all over the body, and general glandular adenopathy. Five minims unfiltered.

May 27th: No perceptible change; gave five minims plain erysipelas toxin; 28th, ten; 29th, fifteen.

June 1st: Having obtained more of Coley's toxins, gave five minims of the unfiltered.

June 2d: Eruption much faded. Gave seven minims of the unfiltered; June 3d, five.

June 8th: Has not received any toxins since June 3d. Been feeling well, but occasionally had severe perspiration at night. Eruptions almost entirely disappeared, and glandular enlargement very slight.

June 9th: Six minims of the unfiltered.

June 10th: Only the very slightest erythema can be perceived on close inspection. Ten minims of the unfiltered given.

From the 11th to the 16th, gave ten minims of the unfiltered; 17th, twelve; 18th, fifteen; 22d, eighteen.

June 23d: No evidence of syphilis.

June 29th: Discharged, with no evidence of syphilis apparent.

Note.—This patient left the city to take a position in Long Branch, with instructions to report to me if he discovered at any time any further evidence of the disease. I have heard nothing from him since and infer that he is sufficiently well to attend to his occupation.

There were three other cases which I wish to mention briefly, though I shall give no detailed history here, for the reason that I discovered that in two of them potassium iodid unknown to me, had been administered while they were receiving treatment by means of the toxins, and the other was under observation for too short a time to determine the effect of the treatment.

Of the two who were treated with the potassium iodid in addition, one of them was an old man in feeble condition when he contracted syphilis, which was very shortly before he came under my observation. His was the only case in which there seemed to be a severe reaction after the administration of the toxins. He had a chill and considerable fever, and in his weak and enfeebled condition I did not think it justifiable to pursue a method of treatment of which we know so little as we do of this. So I put him upon inunctions and a tonic.

The other one had a papular syphilid, which disappeared with great rapidity, but he returned a few days after the last administrations of the toxins with a reappearance of two or three papules, showing that the administration of the toxins had not been efficient in prohibiting a fresh outbreak of cutaneous manifestations.

The third case came to me with persistent papular syphilid of the forehead, and an extensive excoriation of the mucous membrane at the angle of his mouth. His case had resisted ordinary antisyphilitic medication. He was under treatment for a very few days, during which time the papular eruption became very much improved. I could see no change whatever in the excoriation at the angle of the lip.

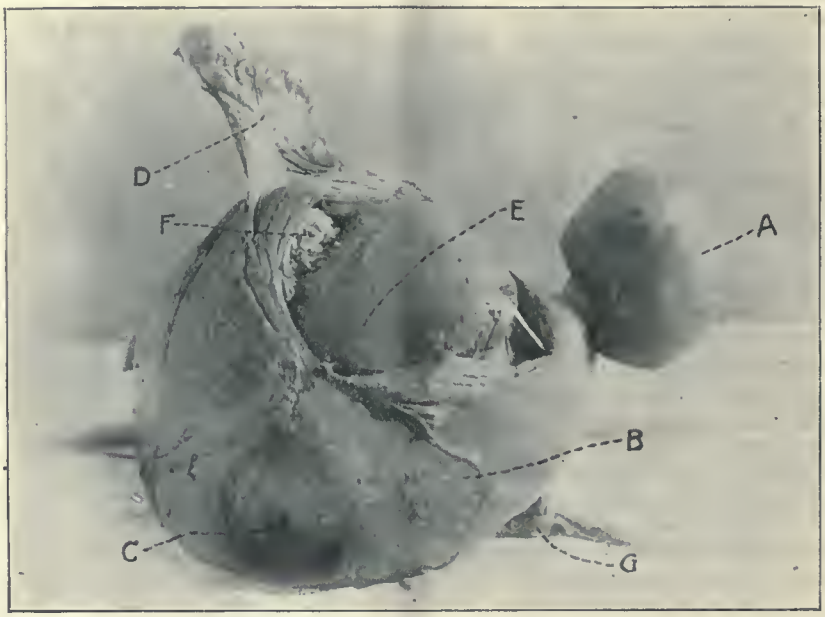
CLINICAL MEMORANDUM.

REPORT OF THREE CASES OF HYSTERECTOMY.

By I. B. PERKINS, M.D.,
of Denver, Col.;
formerly director of gynecological clinic, Denver Medical College, and gynecologist to Arapahoe County Hospital.

Case I.—*Uterine Fibroma:* Mrs. E., aged thirty-five, American born, married, was never pregnant, dressmaker; gives history of having menstruated first when fourteen years of age, and of having had good health and a normal function up to about eight years ago, when she began to have dysmenorrhea and a prolonged menstrual flow. I saw her first during the winter of 1889 and 1890, and on examination, discovered a tumor about the size of a teacup, apparently occupying the right side of the pelvis, and extending about two or three inches above the pubic arch, and lying to the right of the median line. I could not decide at that examination, which was made without an anesthetic, what the character of the tumor was, but thought it a fibroid, and advised exploratory operation, which was declined. I saw the patient no more until January, 1895, when she consulted me, saying she was ready to have the tumor removed. The tumor appeared to be as large as a pregnant uterus at full term. The patient was not in good condition, being anemic and very nervous, with very profuse hemorrhage at the menstrual period, which lasted from ten to twelve days. Obstinate constipation was present. I put her on tonic treatment and rich diet preparatory to the operation. On the 19th of February, 1895, she was admitted to St. Luke's Hospital, and on the following day I operated. The anesthetic used was chloroform; there being a trace of albumin present in the urine, it was deemed best not to use ether. After rendering the vagina and the external parts thoroughly aseptic, I dilated the os, and introduced a probe, which went up into the uterine cavity its full length, about thirteen inches. This caused a profuse hemorrhage, and, without curetting the uterine cavity (the method I prefer), I douched out the uterus with bichlorid, 1–2000, and put a piece of iodoform gauze in the cervix, crowding it up several inches. The vagina was packed with iodoform

gauze. The patient was then placed in the Trendelenburg position. The first incision was from two inches above the pubic arch nearly to the umbilicus, and putting in my hand, I explored, finding on the right side and attached to the main tumor, a tumor, smooth, except some small nodules, resting against the kidney, about twice the size of a normal kidney. I enlarged the incision to within about two inches of the ensiform cartilage, in all about fourteen inches in length, turned the tumor out, and covered the intestines with sterilized towels, and packed sterilized towels in the upper part of the wound. Beginning outside the ovary and tube, transfixing the broad ligament with the ligature, I continued to the base of the broad ligament, tying the uterine artery when I came to it. I proceeded in like manner on the left side.



MRS. E.—CASE I. POSTERIOR VIEW.

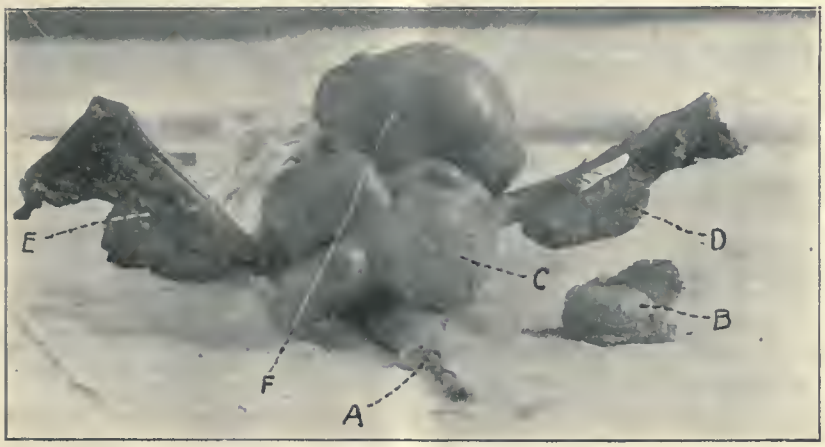
A—Subserous tumor, that was resting over right kidney. B—Shows where posterior flap was taken. C—Shows os uteri. D—Ovary and tube, flattened by pressure. E—Submucous fibroid. F—Gauze, put between wall of uterus and tumor. G—Ovary and tube.

Then with a slight stroke of the bistoury, I cut through the peritoneum, making a semicircular flap posteriorly. (B, photograph 1.) I then dissected this flap down to the cervico-vaginal juncture, then, with a sound in the bladder as a guide, manipulated by an assistant, I took my anterior flap, going about one or two inches above the junction of the bladder with the uterus, and dissected this down also. The next step was to sever the uterus from the vagina at its juncture, going into the posterior cul-de-sac first, an assistant's finger in the vagina as a guide. The uterus was separated completely, and the top of the vagina at once closed with sterilized catgut. The cavity or cup formed by the flaps of peritoneum was then sponged out until quite dry, the peritoneal flaps united by continuous lock-stitch suture of medium-sized catgut. The abdomen was then washed out with normal salt solution, sponged with sterilized sponges, and the abdominal incision closed with interrupted sutures of silkworm-gut, about one-half inch apart, transfixing with the same suture the peritoneum, muscles and skin; dressed with iodoform, iodoform gauze, sterilized gauze and cotton, and held in place by adhesive strips and a bandage. I also put the same kind of dressing over the vulva, held by a T-bandage.

During the operation, several hypodermic injections of strychnin, one-twenty-fifth of a grain, were given, and this was kept up at intervals of two hours for several days; also an occasional hypodermic of nitroglycerin, one-hundredth of a grain, was given. Nutritive enemata: First whisky and black coffee, afterward whisky and peptonized beef juice were kept up for several days. Nothing else in the way of nutrition was given until the bowels moved freely, which was on the third day. The quantity of urine passed the first twenty-four hours was twenty-seven ounces. This, with absence of other symptoms, caused me to feel that no injury had been done the ureters. The patient left the hospital at the end of the third week. Was sitting up and walking a little at the end of five weeks, and at this writing, four months after operation, appears to be in perfect health. The tumor weighed fifteen pounds after removal, and was pronounced a fibroma by Dr. Seebass, who kindly examined it for me.

CASE II.—*Uterine Fibroma:* Mrs. D., aged forty, German, married, never pregnant. Menstruated first at sixteen. Gives history of fainting spells at first three or four menstrual periods. Always flows freely, flow lasts sometimes for seven days. About a year ago she began to fail. Constipation was obstinate, and she had a peculiar affection of speech, by which she would stammer and stop in conservation. In February, 1895, I made an examination and found a tumor, reaching above the pubes,

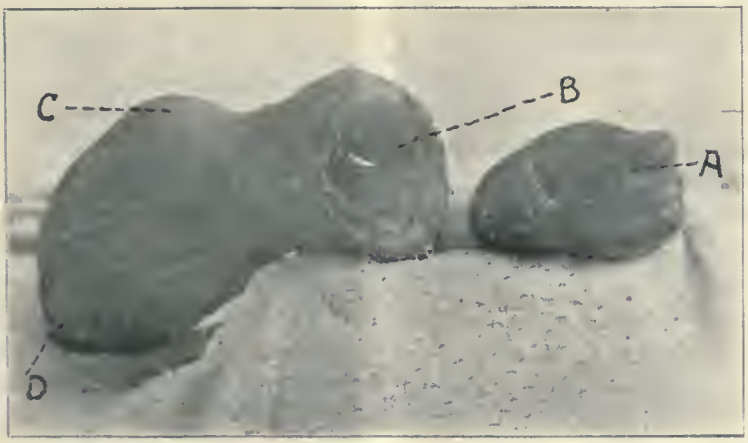
firm, and nodular in shape; nodules could be felt through the vagina, rectum, and abdomen. I advised exploratory operation. She was admitted to St. Luke's Hospital, April 5th, and operated upon April 6, 1895. I made a small incision in median line just above the pubes, and explored, finding a firm, nodular tumor, very irregular in shape, which could only be removed by complete extirpation. I enlarged the opening almost to the umbilicus, and removed the uterus and ovaries, much as described in Case No. 1, except that the peritoneum in this case was found very friable, tearing in several places, and bleeding freely as I ligated down through the broad ligaments. When I attempted to take my flaps, I found it impossible to get one on account of the peritoneum tearing so easily; so on the posterior surface I dissected off a nodule of the tumor with the flap, thinking I could dissect it out afterward. But when I got below the nodule, the peritoneum again broke through, and I was compelled to take some cervical tissue, and make this, with the top of the vagina, serve for the posterior flap. My anterior flap I began from near the bladder, taking only peritoneum enough for my continuous suture; this, with the other flap, covered over the vaginal opening. The operation was completed as in the other case, and the after-treatment was practically the same. Patient is well and able to walk at the present time. Her speech is good. The faltering noticed before operation being scarcely noticeable since the first week after the operation.



MRS. D.—CASE II. POSTERIOR VIEW.

A—Os, with gauze in it. B—Nodule, dissected off with flap. C—Place from which nodule was taken. D—Ovary, tube, and part of broad ligament. E—Ovary, tube, and part of broad ligament. F—Nodules surrounding uterus.

Case III.— *Diffuse infiltrating carcinoma of the cervix.* This case is one of vaginal hysterectomy. Mrs. L., aged fifty-three, English, mother of ten children; consulted me first nearly eight years ago for profuse hemorrhage, lasting sometimes for two weeks, coming on usually at regular monthly intervals. On examination, I found a fibrous polypus attached to the left side of the uterus, just within the internal os, by a pedicle. I removed it January 21, 1888, with complete cessation of hemorrhage. The patient was well until about six months ago,



MRS. L.—CASE III. POSTERIOR AND LEFT LATERAL VIEW.

A—Tumor taken seven years ago. B—Site of carcinoma. C—Nodule on posterior part of uterus. D—Fundus of uterus.

when she began to flow irregularly, not very profusely at first. She grew worse until about two months ago, when I was consulted. On examination, I found the uterus somewhat above the normal size and quite sensitive. The appearance of the cervix led me to suspect malignant disease, and I took a specimen for examination. Dr. Axtell made the examination for me and pronounced it diffuse infiltrating carcinoma. Patient was admitted to St. Luke's Hospital on the 8th of May, 1888, and operated on the following day. Preparation of the patient was the same as in the other two cases. With a sharp curette I removed all the diseased tissue I could, finding that it extended highest on the right side. After again douching out the vagina and the cavity which I had made in the cervix, I packed the cervix full of iodoform gauze, and closed it with a continuous silk suture, and again douched out the vagina with bichlorid, 1–1000. After this a continuous douch of normal salt solution was used during the operation. I freed the cervix from the vagina by a free incision anteriorly and posteriorly, entering the posterior cul-de-sac first; stitched the peritoneum to the mucous membrane by a continuous suture of sterilized catgut, and then tied off the broad ligaments with catgut, very much as when done from above. The most difficult part of the operation was in freeing the bladder from the uterus, as it was spread out and adherent over a larger space than is usual. The stumps of the broad ligaments were brought down and stitched into the vaginal opening above, thereby closing the peritoneal cavity. In doing this, the left ovary and tube came down in the way and were removed. The vagina was packed with iodoform gauze, and a dressing of iodoform gauze, iodoform and sterilized gauze, and cotton, were put over the vulva and held by the T-bandage. I removed the vaginal tampon on the fourth day, and used a bichlorid wash, 1–4000. The case ran an even course and made a good record, leaving the hospital on the twentieth day.

MEDICAL PROGRESS.

Sterilization of Catgut.—Details of the sterilization of catgut in boiling water after hardening in a solution of formalin have already been widely published. The results have not been in every instance satisfactory, and the matter receives exhaustive treatment at the hands of HOFMEISTER in the last number of the *Beiträge z. klin. Chirurgie* (vol. xvi, p. 775).

Complaints have been made that catgut so prepared kinks up in boiling, or that it loses its strength. Omitting instances in which it has been boiled in soda solution with instruments, instead of in clear water, the failures are mostly due to the fact that the catgut has not been tightly stretched on something during the boiling, or to an imperfect washing out of the formalin. The latter process requires a long time, and the odor of formalin is plainly noticeable in catgut, which is wound in several layers on a spool, even after it has been washed several hours in running water.

Hofmeister's perfected method is as follows: (1) The catgut is wound on a glass plate with slightly projecting edges, so that the gut is free from the sides of the plate and exposed to the circulation of the fluids. The ends of the gut are fastened through holes in the plate. (2) Immersion twelve to forty-eight hours in aqueous formalin two to four per cent. (3) Immersion in flowing water at least twelve hours to free the gut from the formalin. (4) Boiling in water ten to thirty minutes. Ten minutes is amply sufficient. Boiling for an hour weakens the gut somewhat. (5) Hardening and preservation in absolute alcohol containing five per cent. of glycerin and one-tenth per cent. of corrosive sublimate. After the catgut has been washed free from formalin it can be kept in alcohol and sterilized as required. It loses none of its strength—at least not in a month's time.

Experiments on animals have proved that formalin catgut is entirely absorbable, though not as quickly as the ordinary material.

THERAPEUTIC NOTES.

The Employment of Eucain in Ophthalmic Practice.—VOLLERT (*Münchener medicinische Wochenschrift*, 1896, No. 22, p. 516) reports the results of a clinical study of eucain $C_{19}H_{27}NO_4HCl$, the name given a new local anesthetic and said to possess advantages over cocain. The base itself, like cocain, is soluble in water with difficulty; while the hydrochlorate is readily soluble, crystallizing out of water in shining plates, and out of methyl-alcohol in bright prisms. The anesthetic effect is not destroyed by boiling. The salt is only partially soluble in 1–5000 sublimate solution at ordinary temperature. The precipitate is dissolved by heat to be deposited again on cooling. A five per cent. solution was employed. The conjunctival irritation, following the instillation of eucain, was more pronounced and more protracted than that due to cocain, and was renewed with each instillation. The anesthetic effect was manifested within two or three minutes, and lasted from eight to twelve minutes. Ocular tension was diminished and mydriasis and cycloparesis resulted, though perhaps not in the same degree as after the use of cocain. The injurious effects upon the epithelium of the conjunctiva and cornea were more pronounced after the use of eucain than after that of cocain.

The Best Chemical Treatment of Lupus.—DUBREUITH & BERNARK (*Monatsch. f. Prac. Dermatol.*, vol. xxii, part 3) strongly advocate early and complete excision of lupus, but for those cases where such treatment is impossible they recommend Unna's salicylic creosote plaster mull. The plaster is spread over the whole affected surface, and bandaged tightly in position. The bandage is changed daily. The lupus is destroyed while the sound skin is relatively unaffected. The resulting ulcer fills with granulation, and any yellow islets of lupus are touched with caustic. The temporary results are satisfactory, but recurrence is to be looked for. In lupus sclerosus this salicylic creosote plaster is not advised, as the scar tissue, as well as the active lupus, it destroys.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SIR JOSEPH LISTER'S ADDRESS.

We publish in The News of this week a very complete abstract of the presidential address of Sir Joseph Lister, before the British Association for the Advancement of Science, at its annual meeting in Liverpool, September 16th. No man of our time has been such an epoch maker, in the history of surgery, as Lister. It must have been a rare privilege to hear from the lips of this great but modest member of our profession his simple, dignified narrative of the logical steps by which he reached the final conclusion of his great theory of aseptic surgery. This is the first time that he has made known the history of his investigations, and this authoritative utterance is fraught with absorbing interest to the entire medical and surgical world. Although, in practice, we seem to have departed far from what he regarded as essential features in the system, the underlying principle of infection upon which the system was founded, is more firmly established than ever.

"Antiseptic surgery" and "antisepsis" are rapidly becoming obsolete terms, and even "asepsis" is gradually being superseded by the simple expression—surgical cleanliness. Lister believed in atmospheric infection, but we now know that practically air infection amounts to nothing, and that contact infection embraces it all. It matters little what the external surroundings may be, provided the field of operation is clean and every article that comes in contact with the wound is free from contaminating material.

Lister develops the whole subject in a masterful, entertaining, and instructive manner, and we feel confident that our readers will deem themselves fortunate in finding his address in the columns of the News.

THE CIRRHOTIC DISEASES OF THE LIVER AND DIABETES.

Ever since Bernard's discoveries of the glycogenic function of the liver and the relation between irritation of the nucleus of the pneumogastric nerve and glycosuria, the attention of pathologists has been turned to the liver as a probable source of diabetes. Notwithstanding this fact careful histological studies of the liver in cases of diabetes are by no means numerous. In a very suggestive article by Dr. Pusinelli of Dresden (*Berlin. klin. Wochenschrift*, August 17, 1896), the relation between diabetes mellitus and cirrhosis of the liver is discussed, and the literature of the subject extensively quoted, while, in addition, he enriches it by the report of a case of unusual interest.

The fact that morbid changes in the liver are found in the majority of cases of diabetes is well established. For example, Glénard found them in sixty per cent. of 324 cases, and Ewald concedes their existence as a rule. The latter, however, states that in numerous cases of hepatic cirrhosis, he has neither observed glycosuria nor been able to produce it artificially by administering large quantities of grape sugar. This question then is not whether hepatic changes are present, as a rule, in cases of diabetes, but whether such changes are primary or secondary, *post hoc* or *propter hoc*. A single, carefully studied case, which throws light on this pathological problem, is a welcome contribution, and such a case is furnished by Pusinelli.

The patient was a man, forty-eight years of age, who, in 1887, first manifested signs of hepatic dis-

ease: transient icterus, with enlargement of the liver. A year later, diabetes, previously absent, was detected. This was readily amenable to treatment but, on the whole, may be said to have existed until 1893 when ascites set in.

Without entering into further details the writer would call attention to what is undoubtedly the most important clinical fact in connection with this case, viz: the diminution of the glycosuria in direct ratio with the development of the ascites, and its final disappearance when the abdomen was distended to its utmost. On the other hand, when the intra-abdominal pressure was relaxed by paracentesis the sugar reappeared. Facts, such as these, to which F. A. Hoffmann, in his "Lehrbuch der Constitutionskrankheiten," has already called attention, show the importance of repeated examinations of the urine in cases of hepatic cirrhosis.

The lesion in Pusinelli's case would have been difficult to determine from the symptoms alone. In the chronic enlargement of the liver and spleen and the icterus, it corresponded with the hypertrophic cirrhosis of Hanot and Charcot, but was differentiated by its eventually giving rise to marked ascites. Pusinelli was inclined to classify it under that subvariety of cirrhosis described by Senator as portal cirrhosis with hypertrophy, and the correctness of this view was confirmed by autopsy.

Every clinician is aware that it is impossible to classify every variety of cirrhosis under the two heads of atrophic and hypertrophic. In the opinion of the writer the best division of the cirrhotic diseases of the liver is that proposed by Senator: (1) Portal granular atrophy of the liver (atrophic cirrhosis), (*a*) portal cirrhosis with hypertrophy, (*b*) portal cirrhosis with icterus; (2) biliary cirrhosis with subsequent atrophy, (*a*) biliary cirrhosis with enlargement of spleen; (3) Hanot's hypertrophic cirrhosis with icterus.

There remains another variety of cirrhosis to which attention was first called by Hanot and Chauffard in 1881—the so-called pigmentary cirrhosis which, when combined with diabetes and melanoderma, constitutes a distinct clinical species now universally recognized under the title of *diabète bronzé*. It presents the usual features of cirrhosis, the connective tissue being most abundant around the intralobular veins, with, in addition, marked pigmentation of the cells of the hepatic parenchyma, the interstitial connective tissue and the derma.

From the foregoing it appears evident that the diagnosis of a case of hepatic cirrhosis, as atrophic or hypertrophic, should not be regarded as final, and also that a fruitful field, both of clinical and pathological research, is afforded in the obscure relation between diabetes and morbid changes in the liver.

THE NEW YORK CHARITIES COMMISSIONERS AGAIN.

FROM week to week we have chronicled in the columns of the MEDICAL NEWS the progress of the Commissioners of Charities of New York City in endeavoring to help along the cause of quackery and to place it on a firm foundation in the public hospitals under their jurisdiction. In our issues of June 27th and July 12th, particularly, we showed how a stock company, organized for the sale of a secret remedy for drunkenness, had, through its organizer, chief stockholder, and prime mover, succeeded in hoodwinking the Commissioners to such an extent that they granted to him privileges for experimentation on the helpless poor, that had never before been dreamed of by the most aggressive and aspiring charlatan. Unfortunately, for the sake of their reputations, the Commissioners were not wise in the selection of a concoction for their "trial heat" in experimental quackery, for the monster which they tried to rear up on the pabulum of their official patronage languished, by reason of the exposure in the NEWS, and died of exhaustion nearly one month before the following resolution was put on file:

NEW YORK, September 11, 1896.

RESOLVED, That the resolution of this Board dated May 19, 1896, and subsequent resolutions providing facilities for and setting aside Ward 33 at Bellevue Hospital to be used in the treatment of alcoholism by Dr. I. Oppenheimer, are hereby rescinded. Further action in this matter is suspended, awaiting the receipt of a report on the results of Dr. Oppenheimer's treatment, such report now being in preparation by Commissioner O'Beirne. (Signed) S. C. CROFT,
JOHN P. FAURE,
JAS. R. O'BEIRNE.

The promoter of the scheme, however, had realized his ambition—plenty of free advertising—and his lack of interest in it during its dying days in the hospital was in marked contrast to the ludicrous efforts of the Commissioners to bolster it up sufficiently to get a "last word" from it, which they might hold up to their critics. But, as we warned them at the very outset, they had given the influence and weight of their official position to one of the rankest exuberations of quackery which we have recently seen. They, however, would not be advised, and preferred to flounder around in the nest which they had befouled.

The conclusion of the above resolution is in entire keeping with the straightforwardness (?) of the Commissioners in this matter heretofore. Transformed into frank Anglo-Saxon, however, it means: "Our attempts to mind the business of others have been colossal failures. We dislike to admit it, however, and are not yet ready to do so. In the meantime, we shall hide our heads, ostrich-like, under the wing of Commissioner O'Beirne, he having been largely instrumental in manipulating the practical workings of our little scheme to reform mankind, and at the same time fill the coffers of a certain doctor, who has forgotten his Hippocratic oath."

We, however, have the body of the ostrich in full sight, where a fitting castigation can be administered, but meantime we shall await "the report," which will probably never see the light.

ECHOES AND NEWS.

Tuberculous Cows.—Nearly fifty per cent. of San Francisco dairy cows will have to be slaughtered to stamp out tuberculosis, which is making great havoc among them.

A Tri-State Medical Society Meeting.—The next meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee, will be held in Chattanooga, October 13th, 14th, and 15th.

A New College Building Opened.—The new medical college building of Syracuse University was formally opened October 5th. Dr. Stephen Smith of New York, delivered the address.

An Ether Drunkard.—A shoe-laster, who is a medical graduate, is reported by a Cincinnati paper to be in the habit of using about a quart of sulphuric ether a day, sometimes drinking it and at other times inhaling it.

Depilated by the X-ray.—A Wisconsin man was recently examined at the physical laboratory of the Minnesota State University to have the location of a bullet in his skull determined by the X-ray. On the right side of the head, which had been most exposed to the rays, the hair has all fallen out.

Hydrostatic Abdominal Exploration.—M. Marc Sée, in a communication to the Académie de Médecine, recommends submergence in water for abdominal exploration. The abdominal walls, loaded with fatty matter, tend to come to the surface of the water, thus rendering easy the delimitation of the organs beneath by palpation.

A Threadworm in the Appendix.—Dr. H. T. Williams, of Rochester (N. Y.), in the *Buffalo Medical Journal*, reports a case of appendicitis in which he had operated. In the extreme end of the appendix, surrounded with pus and liquid feces, was found a living female threadworm (*Oxyuris vermicularis*), about three-eighths of an inch in length.

Tuberculosis in the French Army.—As the result of an investigation into the prevalence of tuberculosis in the French army, GRANJUX (*Revue de la Tuberculose*, 1896, No. 2, p. 87) has found that seven men out of every thousand are affected—a proportion higher than prevails in civil life among individuals of corresponding age. The number is about the same in all European armies, but is increasing from year to year. The increase goes hand in hand with the proportion of young recruits and the necessity for training them in the shortest time possible. Tuberculosis in the army is maintained by the entrance into the ranks of those predisposed to the disease and by contagion. To reduce the danger from contagion to the minimum, it is necessary to cleanse and disinfect the barracks periodically, provide cuspidors, control the food-supply, prevent the abuse of alcohol, and avoid physical excesses.

Medical (!) Items in the Lay Press.—Under the above caption, the *Lancet* says: "If we were to reproduce all the curious medical information supplied by the lay press, there would be little room left in our pages for anything else; but the following gem, being short, as well as brilliant, we are tempted to make an exception in its favor: 'A Delicate Surgical Operation.—An eminent German oculist, Professor Deutschman, according to a medical paper, has succeeded in curing blindness by injecting the liquid of a rabbit's eye into the vitreous humor of the human eye. This is considered the most delicate surgical operation ever performed.' The following paragraph has a more serious import. The journal from which it was taken has an enormous circulation, and the distorted remarks ascribed to Professor Ray Lankester may do a vast amount of harm: 'Filtered Water is a Mistake! We live and learn! Professor Ray Lankester made some remarks recently about drinking-water at the Royal Institute. He told his hearers that if they wanted to dodge cholera and typhoid, and such like unpleasant things, they had better imbibe good rich Thames water, neither boiled nor filtered. River-water of that kind, he said, is safer to drink, for the very reason that it is teeming

with microbes of various species, which prey upon each other, and so give the human organism a chance, whereas in pure spring- or lake-water the typhoid germ, for example, flourishes unmolested by the harmless bacteria, whose function is that of killing disease-germs, so that typhoid has a clear field.' " Ridiculous enough, it is true, but hardly to be compared with the excerpts that might be made from the Sunday editions of a few of the New York papers.

The Jubilee of Anesthesia.—The commemoration of the fiftieth anniversary of the first public demonstration of surgical anesthesia will be held at the Massachusetts General Hospital, Boston, October 16, 1896. The guests will be received in the old amphitheater of the hospital, which will be restored, as far as possible, to its condition at the time of the first operation under ether by Dr. John C. Warren. The following is a program of the public exercises, which will be held in the new amphitheater: Address of welcome, by Charles H. Dalton, president of the hospital; "Reminiscences of 1846," by Dr. R. T. Davis of Fall River, and Dr. Washington Ayer of San Francisco; "Surgery before Anesthesia," by Dr. John Ashhurst, Jr., of Philadelphia; "What Anesthesia has Done for Surgery," by Dr. David W. Cheever of Boston; "Relation of Anesthesia and Obstetrics," by Dr. John P. Reynolds of Boston; "The Influence of Anesthesia upon Medical Science," by Dr. W. H. Welch of Baltimore; "The Surgery of the Future," by Dr. Charles McBurney of New York; "The Birth and Death of Pain" (a poem), by Dr. S. Weir Mitchell of Philadelphia.

British Association Gleanings.—The British Association, which, at its annual meetings, formerly afforded a platform for the first announcement of important scientific discoveries, now rather summarizes the progress of human knowledge during the year. The following are culled from the subjects presented to the Association: Professor Ramsay described the division of helium into two portions, one of which is lighter than the other, though both give the same spectrum. Dr. Dawson Turner of Edinburgh reported the results of some experiments to obtain a form of radiation from glow-worms. He confined them in vessels over sensitive photographic plates, carefully protected from ordinary light by being wrapped tightly in paper. He had great difficulty in getting the insects to glow. The photographic plate was affected, and he thought the glow-worms, even when not visibly glowing, were able to give off rays similar to the X-ray, and capable of penetrating black paper. Dr. McKendrick of Glasgow, in a paper on the phonograph, showed that the hands, when placed in troughs containing salt water, through which an electrical current from the phonograph was passing, received a rhythmical stimulation. He thought that by a proper development of these vibrations deaf persons would thus be enabled to enjoy at least the rhythm of music. Dr. W. Marat showed that respiration in cycling was easier than in walking. Professor Lorrain Smith read a paper written jointly by himself and Professor F. F. Westbrook, on fever in mice. In infected mice there was never obtained any increase in the excretion of nitrogen sufficient to warrant the inference that the metabolism had been disturbed. Supplied with dry biscuit as food, the amount of nitrogen consumed per kilogram was about twenty times as great as that of man. Dr. J. L. Bunch read a paper on the nerves of the intestines, and the effects of small doses of nicotin upon them, in which he showed that if means were taken to eliminate its action on the heart, stimulation of the peripheral cut end of the vagus was found not to influence the intestinal movements, and that intravenous injections of small doses of nicotin put the nerve-roots out of action before the splanchnics. Dr. Pavy, in a paper on the glucosid constitution of the proteid, referred to his "Physiology of the Carbohydrates," in which he had adduced evidence to show that proteid matter, whether animal or vegetable, was a glucosid. By the agency of potash, the amylose carbohydrate, corresponding with Lanchvaro's animal gum, was obtained from a number of animal and vegetable proteids. Treating this with sulphuric acid, sugar was obtained.

SPECIAL ARTICLE.

SIR JOSEPH LISTER'S PRESIDENTIAL ADDRESS BEFORE THE BRITISH ASSOCIATION.[1]

THE presidential address, always noteworthy, of the British Association for the Advancement of Science, has a special interest for the medical profession this year, as it was delivered by Sir Joseph Lister, who spoke upon the interdependence of science and the healing art.

THE RÖNTGEN RAYS.

"The surgeon never performs an operation without the aid of anatomy and physiology; and in what is often the most difficult part of his duty, the selection of the right course to follow, he, like the physician, is guided by pathology, the science of the nature of disease, which, though very difficult from the complexity of its subject-matter, has made during the last half-century, astonishing progress, so that the practice of medicine, in every department, is becoming more and more based on science as distinguished from empiricism. I propose, on the present occasion, to bring before you some illustrations of the interdependence of science and the healing art; and the first that I will take is perhaps the most astonishing of all results of purely physical inquiry—the discovery of the Röntgen rays, so-called after the man who first clearly revealed them to the world. Mysterious as they still are, there is one of their properties which we can all appreciate—their power of passing through substances opaque to ordinary light. There seems to be no relation whatever between transparency in the common sense of the term and penetrability to these emanations. The glasses of a pair of spectacles may arrest them, while a wooden and leathern case allows them to pass almost unchecked; yet they produce, whether directly or indirectly, the same effects as light upon a photographic plate. As a general rule, the denser any object is, the greater obstacle does it

[1] Delivered before the British Association for the Advancement of Science, Liverpool, September 16, 1896.

oppose to the rays. Hence as bone is denser than flesh, if the hand or other part of the body is placed above the sensitive film enclosed in a case of wood or other light material at a suitable distance from the source of the rays, while they pass with the utmost facility through the uncovered parts of the lid of the box and powerfully affect the plate beneath, they are arrested to a large extent by the bones, so that the plate is little acted upon in the parts opposite to them, while the portions corresponding to the muscles and other soft parts are influenced in an intermediate degree. Thus, a picture is obtained in which the bones stand out in sharp relief among the flesh, and anything abnormal in their shape or position is clearly displayed.

"I need hardly point out what important aid this must give to the surgeon. As an instance, I may mention a case which occurred in the practice of Mr. Howard Marsh. He was called to see a severe injury of the elbow, in which the swelling was so great as to make it impossible for him, by ordinary means of examination, to decide whether he had to deal with a fracture or dislocation. If it were the latter, a cure would be effected by the exercise of violence, which would be not only useless, but most injurious, if a bone was broken. By the aid of the Röntgen rays a photograph was taken, in which the bone of the upper arm was clearly seen displaced forward on those of the forearm. The diagnosis being thus established, Mr. Marsh proceeded to reduce the dislocation; and his success was proved by another photograph, which showed the bones in their natural relative position.

"The common metals, such as lead, iron, and copper, being still denser than the osseous structures, these rays can show a bullet imbedded in a bone or a needle lodged about a joint. At the last conversazione of the Royal Society, a picture produced by the new photography displayed with perfect distinctness through the bony framework of the chest a halfpenny low down in a boy's gullet. It had been there for six months, causing uneasiness at the pit of the stomach during swallowing; but whether the coin really remained impacted, or, if so, what was its position, was entirely uncertain till the Röntgen rays revealed it. Dr. Macintyre of Glasgow, who was the photographer, informs me that when the presence of the halfpenny had been thus demonstrated, the surgeon in charge of the case made an attempt to extract it, and although this was not successful in its immediate object, it had the effect of dislodging the coin, for a subsequent photograph by Dr. Macintyre not only showed that it had disappeared from the gullet, but also, thanks to the wonderful penetrating power which the rays had acquired in his hands, proved that it had not lodged further down in the alimentary passage. The boy has since completely recovered.

"The Röntgen rays cause certain chemical compounds to fluoresce and emit a faint light, plainly visible in the dark; and if they are made to fall upon a translucent screen impregnated with such a salt, it becomes beautifully illuminated. If a part of the human body is interposed between the screen and the source of the rays, the bones and other structures are thrown in shadow upon it, and thus a diagnosis can be made without the delay involved in taking a photograph. It was, in fact, in this way, that Dr. Macintyre first detected the coin in the boy's gullet. Mr. Herbert Jackson of King's College, London, early distinguished himself in this branch of the subject. There is no reason to suppose that the limits of the capabilities of the rays in this way have yet been reached. By virtue of the greater density of the heart than the adjacent lungs, with their contained air, the form and dimensions of that organ in the living body may be displayed on the fluorescent screen, and even its movements have been lately seen by several different observers.

"Such important applications of the new rays to medical practice have strongly attracted the interest of the public to them, and I venture to think that they have even served to stimulate the investigations of physicists. The eminent Professor of Physics in the University College of this city (Professor Lodge) was one of the first to make such practical applications, and I was able to show to the Royal Society at a very early period a photograph, which he had the kindness to send me, of a bullet imbedded in the hand. His interest in the medical aspect of the subject remains unabated, and at the same time he has been one of the most distinguished investigators of its purely physical side.

"There is another way in which the Röntgen rays connect themselves with physiology, and may possibly influence medicine. It is found that if the skin is long exposed to their action, it becomes very much irritated—affected with a sort of aggravated sunburning. This suggests the idea that the transmission of the rays through the human body may be not altogether a matter of indifference to internal organs, but may, by long-continued action, produce, according to the condition of the part concerned, injurious irritation of salutary stimulation.

ANESTHESIA IN SURGERY.

"This is the jubilee of anesthesia in surgery. That priceless blessing to mankind came from America. It had, indeed, been foreshadowed in the first year of this century by Humphry Davy, who, having found a toothache from which he was suffering relieved as he inhaled laughing gas (nitrous oxid), threw out the suggestion that it might perhaps be used for preventing pain in surgical operations. But it was not till, on September 30, 1846, Dr. W. T. G. Morton of Boston, after a series of experiments upon himself and the lower animals, extracted a tooth painlessly from a patient whom he had caused to inhale the vapor of sulphuric ether, that the idea was fully realized. He soon afterward publicly exhibited his method at the Massachusetts General Hospital, and after that event the great discovery spread rapidly over the civilized world. I witnessed the first operation in England under ether. It was performed by Robert Liston in University College Hospital, and it was a complete success. Soon afterward I saw the same great surgeon amputate the thigh as painlessly, with less complicated anesthetic apparatus, by aid of another agent, chloroform, which was being powerfully advocated as a substitute for ether by Dr. (afterward Sir James Y.) Simpson, who also had the great merit of showing that confinements could be conducted painlessly, yet safely, under its influence. These

two agents still hold the field as general anesthetics for protracted operations, although the gas originally suggested by Davy, in consequence of its rapid action, and other advantages, has taken their place in short operations, such as tooth-extraction. In the birthplace of anesthesia ether has always maintained its ground; but in Europe it was, to a large extent, displaced by chloroform till recently, when many have returned to ether, under the idea that, though less convenient, it is safer. For my own part, I believe that chloroform, if carefully administered on right principles, is, on the average, the safer agent of the two. The discovery of anesthesia inaugurated a new era in surgery. Not only was the pain of operations abolished, but the serious, and sometimes mortal, shock which they occasioned to the system was averted, while the patient was saved the terrible ordeal of preparing to endure them. At the same time the field of surgery became widely extended, since many procedures in themselves desirable, but, before, impossible from the protracted agony they would occasion, became matters of routine practice. Nor have I by any means exhausted the list of the benefits conferred by this discovery. Anesthesia in surgery has been, from the first to last, a gift of science. Nitrous oxid, sulphuric ether, and chloroform are all artificial products of chemistry; their employment as anesthetics was the result of scientific investigation, and their administration, far from being, like the giving of a dose of medicine, a matter of rule of thumb, imperatively demands the vigilant exercise of physiological and pathological knowledge. While rendering such signal service to surgery, anesthetics have thrown light upon biology generally. It has been found that they exert their soporific influence not only upon vertebrata, but upon animals so remote in structure from man as bees and other insects. Even the functions of vegetables are suspended by their agency. They thus afford strong confirmation of the great generalization that living matter is of the same essential nature wherever it is met with on this planet, whether in the animal or vegetable kingdom. Anesthetics have also, in ways to which I need not here refer, powerfully promoted the progress of physiology and pathology."

He then described the researches on fermentation, whereby Pasteur demonstrated that the breaking up of the sugar into alcohol and carbonic acid was due to the growth of a microörganism, and the experiments of the same investigator to prove the fallacy of spontaneous generation.

THE INTRODUCTION OF ANTISEPSIS.

"Pasteur pointed out the enormous importance of these humble organisms in the economy of nature. It is by their agency that the dead bodies of plants and animals are resolved into simpler compounds fitted for assimilation by new living forms. Without their aid the world would be, as Pasteur expresses it, *encombré de cadavres*. They are essential, not only to our well-being, but to our very existence. Similar microbes must have discharged the same necessary function of removing refuse and providing food for successive generations of plants and animals during the past periods of the world's history; and it is interesting to think that organisms as simple as can well be conceived to have existed when life first appeared upon our globe have, in all probability, propagated the same lowly, but most useful offspring during the ages of geological time.

"Pasteur's labors on fermentation have had a very important influence upon surgery. I have been often asked to speak on my share in this matter before a public audience, but I have hitherto refused to do so, partly because the details are so entirely technical, but chiefly because I have felt an invincible repugnance to what might seem to savor of self-advertisement. The latter objection now no longer exists, since advancing years have indicated that it is right for me to leave to younger men the practice of my dearly loved profession. And it will perhaps be expected that, if I can make myself intelligible, I should say something upon the subject on the present occasion.

"Nothing was formerly more striking in surgical experience than the difference in the behavior of injuries according to whether the skin was implicated or not. Thus, if the bones of the leg were broken and the skin remained intact, the surgeon applied the necessary apparatus without any other anxiety than that of maintaining a good position of the fragments, although the internal injury to the bones and soft parts might be very severe. If, on the other hand, a wound of the skin was present, communicating with the broken bones, although the damage might be in other respects comparatively slight, the compound fracture, as it was termed, was one of the most dangerous accidents that could happen. Mr. Syme, who was, I believe, the safest surgeon of his time, once told me that he was inclined to think that it would be, on the whole, better if all compound fractures of the leg were subjected to amputation, without any attempt to save the limb. What was the cause of this astonishing difference? It was clearly, in some way, due to the exposure of the injured parts to the external world. One obvious effect of such exposure was indicated by the odor of the discharge, which showed that the blood in the wound had undergone putrefactive change, by which the bland nutrient liquid had been converted into highly irritating and poisonous substances. I have seen a man with compound fracture of the leg die within two days of the accident, as plainly poisoned by the products of putrefaction as if he had taken a fatal dose of some potent toxic drug.

"An external wound of the soft parts might be healed in one of two ways. If its surfaces were clean-cut and could be brought into accurate apposition, it might unite rapidly and painlessly 'by the first intention.' This, however, was exceptional. Too often the surgeon's efforts to obtain primary union were frustrated; the wound inflamed and the retentive stitches had to be removed, allowing it to gape, and then, as if it had been left open from the first, healing had to be effected in the other way, which it is necessary for me briefly to describe. An exposed raw surface became covered in the first instance with a layer of clotted blood or certain of its constituents, which invariably putrefied; and the irritation of the sensitive tissues by the putrid products appeared to me to account sufficiently for the inflammation which always occurred in and

around an open wound during the three or four days which elapsed before what were termed 'granulations' had been produced. These constituted a coarsely granular coating of very imperfect or embryonic structure, destitute of sensory nerves and prone to throw off matter or pus, rather than absorb, as freshly divided tissues do, the products of putrefaction. The granulations thus formed a beautiful living plaster, which protected the sensitive parts beneath from irritation and the system generally from poisoning and consequent febrile disturbance. The granulations had other useful properties, of which I may mention their tendency to shrink as they grew, thus gradu-reducing the dimensions of the sore. Meanwhile, another cause of its diminution was in operation. The cells of the epidermis, or scarfskin of the cutaneous margins, were perpetually producing a small crop of young cells of similar nature, which gradually spread over the granulations till they covered them entirely, and a complete cicatrix or scar was the result. Such was the other mode of healing that, by granulation and cicatrization, a process which, when it proceeded unchecked to its completion, commanded our profound admiration. It was, however, essentially tedious, compared with primary union, while, as we have seen, it was always preceded by more or less inflammation and fever, sometimes very serious in their effects. It was also liable to unforseen interruptions; the sore might become larger, instead of smaller, cicatrization giving place to ulceration in one of its various forms, or even to the frightful destruction of tissue which, from the circumstance that it was most frequently met with in hospitals, was termed hospital gangrene. Other serious, and often fatal, complications might arise, which the surgeon could only regard as untoward accidents, and over which he had no efficient control.

"It will be readily understood from the above description that the inflammation which so often frustrated the surgeon's endeavors after primary union was, in my opinion, essentially due to decomposition of blood within the wound.

"These and many other considerations had long impressed me with the greatness of the evil of putrefaction in surgery. I had done my best to mitigate it by scrupulous ordinary cleanliness and the use of various deodorant lotions. But to prevent it altogether appeared hopeless, while we believed with Liebig that its primary cause was the atmospheric oxygen which, in accordance with the researches of Graham, could not fail to be perpetually diffused through the porous dressings which were used to absorb the blood discharged from the wound. But when Pasteur had shown that putrefaction was a fermentation caused by the growth of microbes, and that these could not arise *de novo* in the decomposable substance, the problem assumed a more hopeful aspect. If the wound could be treated with some substance which, without doing too serious mischief to the human tissues, would kill the microbes already contained in it, and prevent the future access of others in the living state, putrefaction might be prevented, however freely the air with its oxygen might enter. I had heard of carbolic acid as having a remarkable deodorizing effect upon sewage, and having obtained from my colleague, Dr. Anderson, Professor of Chemistry in the University of Glasgow, a sample which he had of this product, then little more than a chemical curiosity in Scotland, I determined to try it in compound fractures. Applying it undiluted to the wound, with an arrangement for its occasional renewal, I had the joy of seeing these formidable injuries follow the same safe and tranquil course as simple fractures, in which the skin remains unbroken.

"At the same time we had the intense interest of observing in open wounds what had previously been hidden from human view—the manner in which subcutaneous injuries are repaired. Of special interest was the process by which portions of tissue killed by the violence of the accident were disposed of, as contrasted with what had till then been invariably witnessed. Dead parts had been always seen to be gradually separated from the living by an inflammatory process and thrown off as sloughs. But when protected by the antiseptic dressing from becoming putrid, and therefore irritating, a structure deprived of its life, caused no disturbance in its vicinity; and on the contrary, being of a nutritious nature, it served as pabulum for the growing elements of the neighboring living structures, and these became in due time entirely substituted for it. Even dead bone was seen to be thus replaced by living osseous tissue. This suggested the idea of using threads of dead animal tissue for tying blood vessels; and this was realized by means of catgut, which is made from the intestine of the sheep. If deprived of living microbes, and otherwise properly prepared, catgut answers its purpose completely; the knot holding securely, while the ligature around the vessel becomes gradually absorbed and replaced by a ring of living tissue. The threads, instead of being left long, as before, could now be cut short, and the tedious process of separation of the ligature, with its attendant serious danger of bleeding, was avoided.

"Undiluted carbolic acid is a powerful caustic; and although it might be employed in compound fracture, where some loss of tissue was of little moment in comparison with the tremendous danger to be averted, it was altogether unsuitable for wounds made by the surgeon. It soon appeared, however, that the acid would answer the purpose aimed at, though used in diluted forms devoid of caustic action, and, therefore, applicable to operative surgery. According to our then existing knowledge, two essential points had to be aimed at: to conduct the operation so that on its completion the wound should contain no living microbes; and to apply a dressing capable of preventing the access of other living organisms till the time should have arrived for changing it. Carbolic acid lent itself well to both these objects. Our experience with this agent brought out what was, I believe, a new principle in pharmacology—namely, that the energy of action of any substance upon the human tissues depends not only upon the proportion in which it is contained in the material used as a vehicle for its administration, but also upon the degree of tenacity with which it is held by its solvent. Water dissolves carbolic acid sparingly and holds it extremely lightly, leaving it free to act energetically on other things for which it has greater affinity, while

various organic substances absorb it greedily and hold it tenaciously. Hence its watery solution seemed admirably suited for a detergent lotion to be used during the operation, for destroying any microbes that might fall upon the wound, and for purifying the surrounding skin, and also the surgeon's hands and instruments. For the last-named purpose it had the further advantage that it did not act on steel.

"For an external dressing the watery solution was not adapted, as it soon lost the acid it contained, and was irritating while it lasted. For this purpose some organic substances were found to answer well. Large proportions of the acid could be blended with them in so bland a form as to be unirritating; and such mixtures, while perpetually giving off enough of the volatile salt to prevent organic development in the discharges that flowed past them, served as a reliable store of the antiseptic for days together.

"The appliances which I first used for carrying out the antiseptic principle were both rude and needlessly complicated. The years that have since passed have witnessed great improvements in both respects. Of the various materials which have been employed by myself and others, and their modes of application, I need say nothing except to express my belief, as a matter of long experience, that carbolic acid, by virtue of its powerful affinity for the epidermis and oily matters associated with it, and also its great penetrating power, is still the best agent at our disposal for purifying the skin around the wound. But I must say a few words regarding a most important simplification of our procedure. Pasteur, as we have seen, had shown that the air of every inhabited room teems with microbes; and for a long time I employed various more or less elaborate precautions against the living atmospheric dust, not doubting that, as all wounds except the few which healed completely by the first intention underwent putrefactive fermentation, the blood must be a peculiarly favorable soil for the growth of putrefactive microbes. But I afterward learned that such was by no means the case. I had performed many experiments in confirmation of Pasteur's germ-theory, not indeed in order to satisfy myself of its truth, but in the hope of convincing others. I had observed that uncontaminated milk, which would remain unaltered for an indefinite time if protected from dust, was made to teem with microbes of different kinds by a very brief exposure to the atmosphere, and that the same effect was produced by the addition of a drop of ordinary water. But when I came to experiment with blood drawn with antiseptic precautions into sterilized vessels, I saw, to my surprise, that it might remain free from microbes, in spite of similar access of air or treatment with water. I even found that if very putrid blood was largely diluted with sterilized water, so as to diffuse its microbes widely and wash them of their acrid products, a drop of such dilution added to pure blood might leave it unchanged for days at the temperature of the body, although a trace of the septic liquid undiluted caused intense putrefaction within twenty-four hours. Hence I was led to conclude that it was the grosser forms of septic mischief, rather than microbes in the attenuated condition in which they existed in the atmosphere, that we had to dread in surgical practice. And at the London Medical Congress, in 1881, I hinted, when describing the experiments I have alluded to, that it might turn out possible to disregard altogether the atmospheric dust. But greatly as I should have rejoiced at such a simplification of our procedure, if justifiable, I did not then venture to test it in practice. I knew that with the safeguards which we then employed I could insure the safety of my patients, and I did not dare to imperil it by relaxing them. There is one golden rule for all experiments upon our fellow men. Let the thing tried be that which, according to our best judgment, is the most likely to promote the welfare of the patient. In other words, do as you would be done by.

"Nine years later, however, at the Berlin Congress, in 1890, I was able to bring forward what was, I believe, absolute demonstration of the harmlessness of the atmospheric dust in surgical operations. This conclusion has been justified by subsequent experience; the irritation of the wound by antiseptic irrigation and washing may therefore now be avoided, and nature left undisturbed to carry out her best methods of repair, while the surgeon may conduct his operations as simply as in former days, provided always that, deeply impressed with the tremendous importance of his object, and inspiring the same conviction in all his assistants, he vigilantly maintains from first to last, with care that, once learned, becomes instinctive, but for the want of which nothing else can compensate, the use of the simple means which will suffice to exclude from the wound the coarser forms of septic impurity.

"Even our earlier and ruder methods of carrying out the antiseptic principle soon produced a wonderful change in my surgical wards in the Glasgow Royal Infirmary, which, from being some of the most unhealthy in the kingdom, became, as I believe I may say without exaggeration, the healthiest in the world; while other wards, separated from mine only by a passage a few feet broad, where former modes of treatment were for a while continued, retained their former insalubrity. This result, I need hardly remark, was not in any degree due to special skill on my part, but simply to the strenuous endeavor to carry out strictly what seemed to me a principle of supreme importance.

"Equally striking changes were afterward witnessed in other institutions. Of these I may give one example. In the great Allgemeines Krankenhaus, of Munich, hospital gangrene had become more and more rife from year to year, till at length the frightful condition was reached that eighty per cent. of all wounds became affected by it. It is only just to the memory of Professor von Nussbaum, then the head of the establishment, to say that he had done his utmost to check this frightful scourge; and that the evil was not caused by anything peculiar in his management, was shown by the fact that in a private hospital under his care there was no unusual unhealthiness. The larger institution seemed to have become hopelessly infected, and the city authorities were contemplating its demolition and reconstruction. Under these circumstances, Professor von Nussbaum dispatched his chief assistant, Dr.

Lindpaintner, to Edinburgh, where I at that time occupied the chair of clinical surgery, to learn the details of the antiseptic system as we then practised it. He remained until he had entirely mastered them, and after his return all the cases were on a certain day dressed on our plan. From that day forward not a single case of hospital gangrene occurred in the Krankenhaus. The fearful disease pyemia likewise disappeared, and erysipelas soon followed its example.

"But it was by no means only in removing the unhealthiness of hospitals that the antiseptic system showed its benefits. Inflammation being suppressed, with attendant pain, fever, and wasting discharge, the sufferings of the patient were, of course, immenseiy lessened; rapid primary union being now the rule, convalescence was correspondingly curtailed; while as regards safety and the essential nature of the mode of repair, it became a matter of indifference whether the wound had clean-cut surfaces which could be closely approximated, or whether the injury inflicted had been such as to cause destruction of tissue. And operations which had been regarded from time immemorial as unjustifiable were adopted with complete safety.

"It pleases me to think that there is an ever-increasing number of practitioners throughout the world to whom this will not appear the language of exaggeration. There are cases in which, from the situation of the part concerned or other unusual circumstances, it is impossible to carry out the antiseptic system completely. These, however, are quite exceptional; and even in them much has been done to mitigate the evil which cannot be altogether avoided.

"I ask your indulgence if I have seemed to dwell too long upon matters in which I have been personally concerned. I now gladly return to the labors of others.

BACTERIA THE CAUSE OF DISEASE.

"The striking results of the application of the germ-theory to surgery, acted as a powerful stimulus to the investigation of the nature of the microörganisms concerned; and it soon appeared that putrefaction was by no means the only evil of microbic origin to which wounds were liable. I had myself very early noticed that hospital gangrene was not necessarily attended by any unpleasant odor; and I afterward made a similar observation regarding the matter formed in a remarkable epidemic of erysipelas in Edinburgh, obviously of infective character. I had also seen a careless dressing followed by the occurrence of suppuration without putrefaction. And as these non-putrefactive disorders had the same self-propagating property as ferments, and were suppressed by the same antiseptic agencies which were used for combating the putrefactive microbes, I did not doubt that they were of an analogous origin; and I ventured to express the view that, just as the various fermentations had each its special microbe, so it might be with the various complications of wounds. This surmise was afterward amply verified. Professor Ogston of Aberdeen, was an early worker in this field, and showed that in acute abscesses, that is to say, those which run a rapid course, the matter, although often quite free from unpleasant odor, invariably contains microörganisms belonging to the group which, from the spherical form of their elements, are termed micrococci; and these he classed as streptococci or staphylococci, according as they were arranged in chains or disposed in irregular clusters, like bunches of grapes. The German pathologist, Fehleisen, followed with a beautiful research, by which he clearly proved that erysipelas is caused by a streptococcus. A host of earnest workers in different countries have cultivated the new science of bacteriology, and while opening up a wide fresh domain of biology, have demonstrated in so many cases the causal relation between special microörganisms and special diseases, not only in wounds, but in the system generally, as to afford ample confirmation of the induction which had been made by Pasteur, that all infective disorders are of microbic origin.

"Not that we can look forward with anything like confidence to being able to see the *materies morbi* of every disease of this nature. One of the latest of such discoveries has been that by Pfeiffer of Berlin, of the bacillus of influenza, perhaps the most minute of all microörganisms ever yet detected. The bacillus of anthrax, the cause of a plague common among cattle in some parts of Europe, and often communicated to sorters of foreign wool in this country, is a giant as compared with this tiny being; and supposing the microbe of any infectious fever to be as much smaller than the influenza bacillus as this is less than that of anthrax—a by no means unlikely hypothesis—it is probable that it would never be visible to man. The improvements of the microscope, based on the principle established by my father in the earlier part of the century, have apparently nearly reached the limits of what is possible. But that such parasites are really the causes of all this great class of diseases can no longer be doubted.

"The first rational step toward the prevention or cure of disease is to know its cause; and it is impossible to overestimate the practical value of researches, such as those to which I am now referring. Among their many achievements is what may be fairly regarded as the most important discovery ever made in pathology, because it revealed the true nature of the disease which causes more sickness and death in the human race than any other. It was made by Robert Koch, who greatly distinguished himself, when a practitioner in an obscure town in Germany, by the remarkable combination of experimental acuteness and skill, chemical and optical knowledge, and successful micro-photography which he brought to bear upon the illustration of infective diseases of wounds in the lower animals; in recognition of which service, the enlightened Prussian government at once appointed him to an official position of great importance in Berlin. There he conducted various important researches; and at the London Congress, in 1881, he showed to us, for the first time, the bacillus of tubercle. Wonderful light was thrown, by this discovery, upon a great group of diseases which had before been rather guessed than known to be of an allied nature; a precision and efficacy never before possible was introduced into their surgical treatment, while the physi-

cian became guided by new and sure light as regards their diagnosis and prevention.

"At that same London Congress, Koch demonstrated to us his 'plate culture' of bacteria, which was so important that I must devote a few words to its description. With a view to the successful study of the habits and effects of any particular microbe outside the living body, it is essential that it should be present unmixed in the medium in which it is cultivated. It can be readily understood how difficult it must have been to isolate any particular microörganism when it existed mixed, as was often the case, with a multitude of other forms. In fact, the various ingenious attempts made to effect this object had often proved entire failures. Koch, however, by an ingenious procedure, converted what had been before impossible into a matter of the utmost facility. In the broth or other nutrient liquid, which was to serve as food for the growing microbe, he dissolved, by aid of heat, just enough gelatin to insure that, while it should become a solid mass when cold, it should remain fluid, though reduced in temperature so much as to be incapable of killing living germs. To the medium thus partially cooled, was added some liquid containing, among others, the microbe to be investigated; and the mixture was thoroughly shaken so as to diffuse the bacteria and separate them from each other. Some of the liquid was then poured out in a thin layer upon a glass plate and allowed to cool so as to assume the solid form. The various microbes, fixed in the gelatin and so prevented from intermingling, proceeded to develop each its special progeny, which, in course of time, showed itself as an opaque speck in the transparent film. Any one of such specks could now be removed and transferred to another vessel in which the microbe composing it, grew in perfect isolation.

"Pasteur was present at this demonstration, and expressed his sense of the great progress effected by the new method. It was soon introduced into his own institute and other laboratories throughout the world; and it has immensely facilitated bacteriological study.

"One fruit of it in Koch's own hands was the discovery of the microbe of cholera in India, whither he went to study the disease. This organism was termed by Koch from its curved form the 'comma bacillus,' and by the French the cholera vibrio. Great doubts were for a long time felt regarding this discovery. Several other kinds of bacteria were found of the same shape, some of them producing very similar appearances in culture-media. But bacteriologists are now universally agreed that, although various other conditions are necessary to the production of an attack of cholera besides the mere presence of the vibrio, yet it is the essential *materies morbi;* and it is by the aid of the diagnosis which its presence in any case of true cholera enables the bacteriologist to make, that threatened invasions of this awful disease have of late years been so successfully repelled from our shores. If bacteriology had done nothing more for us than this, it might well have earned our gratitude.

PREVENTIVE INOCULATION.

"I have next to invite your attention to some earlier work of Pasteur. There is a disease known in France under the name of *choléra des poules*, which often produced great havoc among the poultry yards of Paris. It had been observed that the blood of birds that had died of this disease were peopled by a multitude of minute bacteria, not very dissimilar in form and size to the microbe of the lactic ferment, to which I have before referred. And Pasteur found that, if this bacterium was cultivated outside the body for a protracted period, under certain conditions, it underwent a remarkable diminution of its virulence; so that, if inoculated into a healthy fowl, it no longer caused the death of the bird, as it would have done in its original condition, but produced a milder form of the disease, which was not fatal. And this altered character of the microbe, caused by certain conditions, was found to persist in successive generations cultivated in the ordinary way. Thus was discovered the great fact, of what Pasteur termed *atténuation des virus*, which at once gave the clue to understanding what had before been quite mysterious, the difference in virulence of the same disease in different epidemics.

"But he made a further very important observation, that a bird which had gone through a mild form of the complaint had acquired immunity against it in its most virulent condition. Pasteur afterward succeeded in obtaining mitigated varieties of microbes for some other diseases; and he applied with great success the principle which he had discovered in fowl-cholera for protecting the larger domestic animals against the plague of anthrax. The preparations used for such preventive inoculations he termed 'vaccins' in honor of our great countryman, Edward Jenner. For Pasteur at once saw the analogy between the immunity to fowl-cholera, produced by its attenuated virus, and the protection afforded against smallpox by vaccination. And while pathologists still hesitated, he had no doubt of the correctness of Jenner's expression *variolæ vaccinæ*, or smallpox in the cow.

"It is just a hundred years since Jenner made the crucial experiment of inoculating with smallpox a boy whom he had previously vaccinated, the result being, as he anticipated, that the boy was quite unaffected.

"While we cannot be astonished that the centenary of Jenner's immortal discovery should have failed to receive general recognition in this country, it is melancholy to think that this year should, in his native county, have been distinguished by a terrible illustration of the results which would sooner or later inevitably follow the general neglect of his prescriptions.

"But to return to Pasteur. In 1880 he entered upon the study of that terrible, but then most obscure disease, hydrophobia or rabies, which, from its infective character, he was sure must be of microbic origin, although no microorganism could be detected in it. He early demonstrated the new pathological fact that the virus had its essential seat in the nervous system. This proved the key to his success in this subject. One result that flowed from it has been the cause of unspeakable consolation to many. The foolish practice is still too prevalent of killing the dog that has bitten any one, on the absurd notion that, if it were mad, its destruction would prevent the occurrence of

hydrophobia in the person bitten. The idea of the bare possibility of the animal having been so affected causes an agony of suspense during the long weeks or months of possible incubation of the disease. Very serious nervous symptoms aping true hydrophobia have been known to result from the terror thus inspired. Pasteur showed that if a little of the brain or spinal cord of a dog that had been really mad was inoculated in an appropriate manner into a rabbit, it infallibly caused rabies in that animal in a few days. If, therefore, such an experiment was made with a negative result, the conclusion might be drawn with certainty that the dog had been healthy. It is perhaps right that I should say that the inoculation is painlessly done under an anesthetic, and that in the rabbit rabies does not assume the violent form that it does in the dog, but produces gradual loss of power, with little, if any suffering.

"This is the more satisfactory because rabbits in which the disease has been thus artificially induced are employed in carrying out what was Pasteur's greatest triumph—the preventive treatment of hydrophobia in the human subject. We have seen that Pasteur discovered that microbes might, under some circumstances, undergo mitigation of their virulence. He afterward found that under different conditions they might have it exalted, or, as he expressed it, there might be a *renforcement du virus*. Such proved to be the case with rabies in the rabbit; so that the spinal cords of animals which had died of it contained the poison in a highly intensified condition. But he also found that if such a highly virulent cord was suspended under strict antiseptic precautions in a dry atmosphere at a certain temperature, it gradually, from day to day, lost its potency, till, in course of time, it became absolutely inert. If now the emulsion of such a harmless cord was introduced under the skin of an animal, as in the subcutaneous administration of morphia, it might be followed without harm another day by a similar dose of a cord still rather poisonous; and so from day to day stronger and stronger injections might be used, the system becoming gradually accustomed to the poison, till a degree of virulence had been reached far exceeding that of the bite of a mad dog. When this had been attained, the animal proved incapable of taking the disease in the ordinary way, and, more than that, if such treatment was adopted after an animal had already received the poison, provided that too long a time had not elapsed, the outbreak of the disease was prevented. It was only after great searching of heart that Pasteur, after consultation with some trusted medical friends, ventured upon trying this practice upon man. It has since been extensively adopted in various parts of the world with increasing success as the details of the method were improved. It is not, of course, the case that every one bitten by a really rabid animal takes the disease, but the percentage of those who do so, which was formerly large, has been reduced almost to zero by this treatment, if not too long delayed.

"While the intensity of rabies in the rabbit is undoubtedly due to a peculiarly virulent form of the microbe concerned, we cannot suppose that the daily diminishing potency of the cord suspended in dry, warm air is an instance of attenuation of virus, using the term 'virus' as synonymous with the microbe concerned. In other words, we have no reason to believe that the special microorganism of hydrophobia continues to develop in the dead cord and produce successively a milder and milder progeny, since rabies cannot be cultivated in the nervous system of a dead animal. We must rather conclude that there must be some chemical poison present which gradually loses its potency as time passes. And this leads me to refer to another most important branch of this large subject of bacteriology, that of the poisonous products of microbes.

THE ANTITOXIN TREATMENT.

"It was shown several years ago by Roux and Yersin, working in the Institut Pasteur, that the crust or false membrane which forms upon the throats of patients affected with diphtheria contains bacteria, which can be cultivated outside of the body in a nutrient liquid, with the result that it acquires poisonous qualities of astonishing intensity, comparable to that of the secretion of the poison-glands of the most venomous serpents. And they also ascertained that the liquid retained this property after the microbes had been removed from it by filtration, which proved that the poison must be a chemical substance in solution, as distinguished from the living element which had produced it. These poisonous products of bacteria, or toxins, as they have been termed, explain the deadly effects of some microbes, which it would otherwise be impossible to understand. Thus, in diphtheria itself the special bacillus which was shown by Loeffler to be its cause does not become propagated in the blood, like the microbe of chicken cholera, but remains confined to the surface on which it first appeared; but the toxin which it secretes is absorbed from that surface into the blood, and so poisons the system. Similar observations have been made with regard to the microbes of some other diseases, as, for example, the bacillus of tetanus or lockjaw. This remains localized in the wound, but forms a special toxin of extreme potency, which becomes absorbed and diffused through the body.

"Wonderful as it seems, each poisonous microbe appears to form its own peculiar toxin. Koch's tuberculin was of this nature—a product of the growth of the tubercle bacillus in culture-media. Here, again, great effects were produced by extremely minute quantities of the substance, but here a new peculiarity showed itself, viz., that patients affected with tubercular disease, in any of its varied forms, exhibited inflammation in the affected part and general fever after receiving under the skin an amount of the material which had no effect whatever upon healthy persons. I witnessed in Berlin some instances of these effects, which were simply astounding. Patients affected with a peculiar form of obstinate ulcer of the face showed, after a single injection of the tuberculin, violent inflammatory redness and swelling of the sore and surrounding skin; and, what was equally surprising, when this disturbance subsided, the disease was found to have undergone great improvement. By repetitions of such procedures, ulcers which had previously been steadily advancing, in spite of ordinary treatment, became greatly

reduced in size and, in some instances, apparently cured. Such results led Koch to believe that he had obtained an effectual means of dealing with tubercular disease in all its forms. Unhappily, the apparent cure proved to be only of transient duration, and the high hopes which had been inspired by Koch's great reputation were dashed. It is but fair to say that he was strongly urged to publish before he was himself disposed to do so, and we cannot but regret that he yielded to the pressure put upon him.

"But though Koch's sanguine anticipations were not realized, it would be a great mistake to suppose that his labors with tuberculin have been fruitless. Cattle are liable to tubercle, and, when affected with it, may become a very serious source of infection for human beings, more especially when the disease affects the udder of cows, and so contaminates the milk. By virtue of the close affinity that prevails between the lower animals and ourselves, in disease as well as in health, tuberculin produces fever in tubercular cows in doses which do not affect healthy beasts. Thus, by the subcutaneous use of a little of the fluid, tubercle latent in internal organs of an apparently healthy cow can be with certainty revealed, and the slaughter of the animal after this discovery protects man from infection.

"It has been ascertained that glanders presents a precise analogy with tubercle as regards the effects of its toxic products. If the microbe which has been found to be the cause of this disease is cultivated in appropriate media it produces a poison which has received the name of mallein, and the subcutaneous injection of a suitable dose of this fluid into a glandered horse causes striking febrile symptoms which do not occur in a healthy animal. Glanders, like tubercle, may exist in insidious latent forms which there was formerly no means of detecting, but which are at once disclosed by this means. If a glandered horse has been accidentaliy introduced into a large stable this method of diagnosis surely tells if it has infected others. All receive a little mallein. Those which become affected with fever are slaughtered, and thus not only is the disease prevented from spreading to other horses, but the grooms are protected from a mortal disorder.

"This valuable resource sprang from Koch's work on tuberculin, which has also indirectly done good in other ways. His distinguished pupil, Behring, has expressly attributed to those researches the inspiration of the work which led him and his famous collaborator, the Japanese Kitasato, to their surprising discovery of antitoxin serum. They found that if an animal of a species liable to diphtheria or tetanus received a quantity of the respective toxin, so small as to be harmless, and afterward, at suitable intervals, successively stronger and stronger doses, the creature, in course of time, acquires such a tolerance for the poison as to be able to receive with impunity a quantity very much greater than would at the outset have proved fatal. So far we have nothing more than seems to correspond with the effects of the increasingly potent cords in Pasteur's treatment of rabies. But what was entirely new in their results was that, if blood was drawn from an animal which had acquired this high degree of artificial immunity, and some of the clear fluid or serum which exuded from it after it had clotted was introduced under the skin of another animal, this second animal acquired a strong, though more transient, immunity against the particular toxin concerned. The serum in some way counteracted the toxin or was antitoxic. But, more than that, if some of the antitoxic serum was applied to an animal after it had already received a poisonous dose of the toxin it preserved the life of the creature, provided that too long a time had not elapsed after the poison was introduced. In other words, the antitoxin proved to be not only preventive but curative.

"Similar results were afterward obtained by Ehrlich of Berlin, with some poisons not of bacterial origin, but derived from the vegetable kingdom; and quite recently the independent labors of Calmette of Lille, and Fraser of Edinburgh, have shown that antidotes of wonderful efficacy against the venom of serpents may be procured on the same principle. Calmette has obtained antitoxin so powerful that a quantity of it only a 200,000th part of the weight of an animal will protect it perfectly against a dose of the secretion of the poison-glands of the most venomous serpents known to exist, which, without such protection, would have proved fatal in four hours. For curative purposes larger quantities of the remedy are required, but cases have already been published by Calmette in which death appears to have been averted in the human subject by this treatment.

"Behring's darling object was to discover means of curing tetanus and diphtheria in man. In tetanus the conditions are not favorable; because the specific bacilli lurk in the depths of the wound, and only declare their presence by symptoms caused by their toxin having been already in a greater or less amount diffused through the system; and in every case of this disease there must be a fear that the antidote may be applied too late to be useful. But in diphtheria the bacilli very early manifest their presence by the false membrane which they cause upon the throat, so that the antitoxin has a fair chance; and here we are justified in saying that Behring's object has been attained.

"The problem, however, was by no means so simple as in the case of some mere chemical poison. However effectual the antitoxin might be against the toxin, if it left the bacilli intact, not only would repeated injections be required to maintain the transient immunity to the poison perpetually secreted by the microbes, but the bacilli might, by their growth and extension, cause obstruction of the respiratory passages.

"Roux, however, whose name must always be mentioned with honor in relation to this subject, effectually disposed of this difficulty. He showed by experiments on animals that a diphtheritic false membrane, rapidly extending and accompanied by surrounding inflammation, was brought to a stand by the use of the antitoxin, and soon dropped off, leaving a healthy surface. Whatever be the explanation, the fact was thus established that the antitoxic serum, while it renders the toxin harmless, causes the microbe to languish and disappear.

"No theoretical objection could now be urged against the

treatment; and it has during the last two years been extensively tested in practice in various parts of the world, and it has gradually made its way more and more into the confidence of the profession. One important piece of evidence in its favor in this country is derived from the report of the six large hospitals under the management of the London Asylums Board. The medical officers of these hospitals at first naturally regarded the practice with skepticism, but as it appeared to be at least harmless they gave it a trial; and during the year 1895 it was very generally employed upon the 2182 cases admitted, and they have all become convinced of its great value. In the nature of things, if the theory of the treatment is correct, the best results must be obtained when the patients are admitted at an early stage of the attack, before there has been time for much poisoning of the system, and accordingly we learn from the report that, comparing 1895 with 1894, during which latter year the ordinary treatment had been used, the percentage of mortality, in all the six hospitals combined, among the patients admitted on the first day of the disease, which in 1894 was 22.5, was only 4.6 in 1895; while for those admitted on the second day the numbers are 27 for 1894 and 14.8 for 1895. Thus, for cases admitted on the first day the mortality was only one-fifth of what it was in the previous year, and for those entering on the second it was halved. Unfortunately, in the lower part of London, which furnish most of these patients, the parents too often delay in sending in the children till much later, so that on an average no less than 67.5 per cent. were admitted on the fourth day of the disease or later. Hence the aggregate statistics of all cases are not nearly so striking. Nevertheless, taking it altogether, the mortality in 1895 was less than had ever before been experienced in these hospitals. I should add that there was no reason to think that the disease was of a milder type than usual in 1895; and no change whatever was made in the treatment except as regards the antitoxic injections.

"There is one piece of evidence recorded in the report which, though it is not concerned with high numbers, is well worthy of notice. It relates to a special institution to which convalescents from scarlet fever are sent from all the six hospitals. Such patients occasionally contract diphtheria, and when they do so the added disease has generally proved extremely fatal. In the five years preceding the introduction of the treatment with antitoxin the mortality from this cause had never been less than 50 per cent., and averaged on the whole 61.9 per cent. During 1895, under antitoxin, the deaths among the 119 patients of this class were only 7.5 per cent., or one-eighth of what had been previously experienced. This very striking result seems to be naturally explained by the fact that these patients, being already in a hospital when the diphtheria appeared, an unusually early opportunity was afforded for dealing with it.

"There are certain cases of so malignant a character from the first that no treatment will probably ever be able to cope with them. But taking all cases together, it seems probable that Behring's hope that the mortality may be reduced to five per cent. will be fully realized when the public have become alive to the paramount importance of having the treatment commenced at the outset of the disease.

"There are many able workers in the field of bacteriology whose names time does not permit me to mention, and to whose important labors I cannot refer; and even those researches of which I have spoken have been, of course, most inadequately dealt with. I feel this especially with regard to Pasteur, whose work shines out more brightly the more his writings are perused.

PHAGOCYTOSIS.

"I have lastly to bring before you a subject which, though not bacteriological, has intimate relations with bacteria. If a drop of blood is drawn from the finger by a prick with a needle and examined microscopically between two plates of glass, there are seen in it minute solid elements of two kinds, the one pale orange biconcave disks, which, seen in mass, give the red color to the vital fluid; the other, more or less granular spherical masses of the soft material called protoplasm, destitute of color, and therefore called the colorless, or white corpuscles. It has been long known that if the microscope was placed at such a distance from the fire as to have the temperature of the human body, the white corpuscles might be seen to put out and retract little processes or pseudopodia, and by their means crawl over the surface of the glass, just like the extremely low forms of animal life, termed, from this faculty of changing their form, amebæ. It was a somewhat weird spectacle, that of seeing what had just before been constituents of our own blood, moving about like independent creatures. Yet there was nothing in this inconsistent with what we know of the fixed components of the animal frame. For example, the surface of a frog's tongue is covered with a layer of cells, each of which is provided with two or more lashing filaments or cilia, and those of all the cells acting in concert cause a constant flow of liquid in a definite direction over the organ. If we gently scrape the surface of the animal's tongue we can detach some of these ciliated cells; and on examining them with the microscope in a drop of water we find that they will continue for an indefinite time their lashing movements, which are just as much living or vital in their character as the writhings of a worm. And, as I observed many years ago, these detached cells behave under the influence of a stimulus just like parts connected with the body, the movement of the cilia being excited to greater activity by gentle stimulation, and thrown into a state of temporary inactivity when the irritation was more severe. Thus each constituent element of our bodies may be regarded as in one sense an independent living being, though all work together in marvelous harmony for the good of the body politic. The independent movements of the white corpuscles outside the body were therefore not astonishing; but they long remained matters of mere curiosity. Much interest was called to them by the observation of the German pathologist Cohnheim, that in some inflammatory conditions they passed through the pores in the walls of the finest blood-vessels, and thus escaped into the inter-

stices of the surrounding tissues. Cohnheim attributed their transit to the pressure of the blood. But why it was that, though larger than the red corpuscles, and containing a nucleus which the red ones have not, they alone passed through the pores of the vessels, or why it was that this emigration of the white corpuscles occurred abundantly in some inflammations and was absent in others, was quite unexplained.

"These white corpuscles, however, have been invested with extraordinary new interest by the researches of the Russian naturalist and pathologist Metchnikoff. He observed that, after passing through the walls of the vessels, they not only crawl about like amebæ, but, like them, receive nutritious materials into their soft bodies and digest them. It is thus that the effete materials of a tadpole's tail are got rid of; so that they play a most important part in the function of absorption.

"But still more interesting observations followed. He found that a microscopic crustacean, a kind of water-flea, was liable to be infested by a fungus, which had exceedingly sharp-pointed spores. These were apt to penetrate the coats of the creature's intestine, and project into its body-cavity. No sooner did this occur with any spore than it became surrounded by a group of the cells which are contained in the cavity of the body and correspond to the white corpuscles of our blood. These proceeded to attempt to devour the spore, and if they succeeded in every such case the animal was saved from the invasion of the parasite. But if the spores were more than could be disposed of by the devouring cells (phagocytes, as Metchnikoff termed them) the water-flea succumbed.

"Starting from this fundamental observation, he ascertained that the microbes of infective diseases are subject to this same process of devouring and digestion, carried on both by the white corpuscles and by cells that line the blood-vessels. And by a long series of most beautiful researches he has, as it appears to me, firmly established the great truth that phagocytosis is the main defensive means possessed by the living body against the invasion of its microscopic foes. The power of the system to produce antitoxic substances to counteract the poisons of microbes is undoubtedly in its own place of great importance. But in the large class of cases in which animals are naturally refractory to particular infective diseases, the blood is not found to yield any antitoxic element by which the natural immunity can be accounted for. Here phagocytosis seems to be the sole defensive agency. And even in cases in which the serum does possess antitoxic, or, as it would seem in some cases, germicidal properties, the bodies of the dead microbes must at last be got rid of by phagocytosis, and some recent observations would seem to indicate that the useful elements of the serum may be, in part at least, derived from the digestive juices of the phagocytes. If ever there was a romantic chapter in pathology, it has surely been that of the story of phagocytosis.

"I was myself peculiarly interested by these observations of Metchnikoff, because they seemed to me to afford clear explanation of the healing of wounds by first intention under circumstances before incomprehensible. This primary union was sometimes seen to take place in wounds treated by water-dressing, that is to say, a piece of wet lint covered with a layer of oiled silk to keep it moist. This, though clean when applied, was invariably putrid within twenty-four hours. The layer of blood between the cut surfaces was thus exposed at the outlet of the wound to a most potent septic focus. How was it prevented from putrefying, as it would have done under such influence if, instead of being between divided living tissues, it had been between plates of glass or other indifferent material? Pasteur's observations pushed the question a step further. It now was, how were the bacteria of putrefaction kept from propagating in the decomposable film? Metchnikoff's phagocytosis supplied the answer. The blood between the lips of the wound became rapidly peopled with phagocytes, which kept guard against the putrefactive microbes, and seized them as they endeavored to enter.

"If phagocytosis was ever able to cope with septic microbes in so concentrated and intense a form, it could hardly fail to deal effectually with them in the very mitigated condition in which they are present in the air. We are thus strongly confirmed in our conclusion that the atmospheric dust may safely be disregarded in our operations, and Metchnikoff's researches, while they have illumined the whole pathology of infective diseases, have beautifully completed the theory of antiseptic treatment in surgery.

"I might have taken equally striking illustrations of my theme from other department in which microbes play no part. In fact, any attempt to speak of all that the art of healing has borrowed from science and contributed to it during the past half-century, would involve a very extensive dissertation on pathology and therapeutics. I have culled specimens from a wide field; and I only hope that in bringing them before you, I have not overstepped the bounds of what is fitting before a mixed company. For many of you, my remarks can have had little, if any, novelty; for others, they may, perhaps, possess some interest as showing that medicine is no unworthy ally of the British Association; that, while her practice is ever more and more based on science, the ceaseless efforts of her votaries to improve what have been fittingly designated *Quæ prosunt omnibus artes* are ever adding largely to the sum of abstract knowledge."

SOCIETY PROCEEDINGS.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-fourth Annual Session held in Buffalo, N. Y., September 15 to 18, 1896.

THE opening session was called to order promptly at 10 o'clock by the president, DR. EDUARDO LICEAGO of Mexico, and after the reports of various committees and other executive business, the regular program was taken up.

The morning was chiefly devoted to the consideration of the problems of the disinfection and sanitation of railroad cars and steamboats, papers being read by DRS. DOMINGO, ORVAÑANOS, City of Mexico; TOMAS NO-

RIEGA, Chinpas, and FREDERICK MONTIYAMBERT of Toronto. The Mexican delegates reported some specially distressing cases of the spreading of contagion by this means, and a brisk discussion as to ways and means of guarding against this source of danger followed.

In the afternoon a group of papers upon meat and milk infections were first presented by DRS. J. F. KENNEDY of Iowa, GARDNER F. SWARTS of Rhode Island, and D. E. SALMON of Washington, D. C.

DR. KENNEDY took the ground that inasmuch as the death-rate among children fed upon cow's milk was much higher than among those suckled at the breast, and this mortality was chiefly due to two things, dilution with water causing death by inanition and infection with various germs, that a most rigid inspection and testing of milk should be insisted upon. But even this might fail, unavoidably, at the most vital point, and, therefore, to ensure absolute safety all milk used by infants should be sterilized. Infection might occur simply by washing the cans with impure water. Tuberculosis was the chief danger, but typhoid, diphtheria, and scarlet fever were also frequently spread through this medium.

DR. SWARTS urged that farms should be established near all cities similar to that in operation near Buffalo where, at the suggestion of a number of physicians, every sanitary precaution was carried out in the dairy, the milk submitted to a bacteriological examination every week, and then certified to by them as pure and suitable for children's use. A higher price (ten cents per quart) had, of course, to be charged for such milk, but this was found to be gladly paid by the more intelligent class of parents that the dairyman had no difficulty in disposing of his entire output, and is talking of increasing the number of his cows to meet the demand.

DR. SALMON'S paper was the report of the committee on

ANIMAL DISEASES AND ANIMAL FOOD.

He urged the necessity of more stringent measures against the spread of anthrax, and of rabies, and of greater legal powers in dealing with the sale of tuberculous meats.

DR. BENJAMIN LEE of Philadelphia, took issue with Dr. Kennedy as to the healthfulness of sterilized milk, which, he declared, was robbed of some of its most valuable nutritive elements, and would cause both rickets and infantile scurvy. Both of these diseases had become much more common since the introduction of the sterilized article.

DR. HIBBARD of Indiana, doubted if any cases of tuberculosis could be positively traced to contaminated milk.

DR. LYMAN of Massachusetts, intimated that the chief danger lay rather in lowered resisting power on the part of the child, and urged pure air, sunlight, and sleep as indispensible safeguards.

DR. HALTON of Vermont, thought we were giving the public exaggerated notions of the danger of tubercular infection through milk.

DR. KINYOUN and DR. SALMON, in closing, cited cases of such infection, and declared the danger in no risk of exaggeration.

Two valuable papers followed upon the nomenclature of

DISEASES AND FORMS OF STATISTICS,

by DRS. EDUARDO LICEAGA, Mexico, and SAMUEL W. ABBOT of Massachusetts, but provoked little discussion.

The evening session, after addresses of welcome by Mayor Jewett and Rev. Thos. Slicer of Buffalo, and response by Dr. Peter Bryce of Toronto, was devoted to the address of the president.

He chose for his subject the history and development of public hygiene in America in general, and in Mexico in particular.

Rapid strides had been made in the last twenty years under the administration and encouragement of President Diaz. The question of the differential study of contagious diseases as to the degree and length of isolation and quarantine in each form, and also as to actual length of time which the infection of each persisted after cure, was taken up in detail, and many valuable suggestions offered. The necessity of a broader study by uniform methods of all the problems of contagion and disinfection over wide areas of country was urged, and the necessity of government inspection and regulation of viruses and serums, for inoculation purposes, insisted upon.

WEDNESDAY, SEPTEMBER 16TH.

After some preliminary announcements and reports, the Association considered the question of the disposal of garbage. The report of the committee on this subject was read by Rudolph Hering, C.E., of New York, and papers followed by Colonel Wm. F. Morse of New York, Dr. N. E. Wordin of Connecticut, and Major Wm. S. Tremaine, U. S. A. The paper of Colonel Morse was especially interesting, and all the readers united substantially in recommending that each household should carbonize its own refuse in some way, and turn it over to the municipal authorities in the shape of ashes. Two of them recommended the use of a box and cradle, which could be attached to or inserted in the kitchen stove-pipe, and Dr. Wordin exhibited two forms of such an apparatus, one with gas-burner attachment. With this latter, it was declared that not only kitchen refuse, but even feces could be completely incinerated without any escape of gases or odors, and the larger sizes could be used in place of water-closets where hydrant-water was not available. Dr. Gihon opened the discussion of the papers with the somewhat startling remark that the best way to dispose of half of our garbage was to eat it. We prepare nearly twice as much food as can reasonably be disposed of and throw away, or permit to spoil nearly half of it. Both economy and sanitation would be promoted if we could take a leaf out the books of the French in this regard.

The discussion was continued by Drs. Sternberg, Lee, Durgin, and Lucien Howe, who, in the main, agreed with the papers that the swill-pail and the garbage-barrel were themselves nuisances, which ought to be abated as much as possible.

Two papers upon

THE TRANSPORTATION AND DISPOSAL OF THE DEAD,

by DRS. CHAS. O. PROBST of Columbus, and BENJ. LEE of Philadelphia, and a brief discussion, completed the morning session.

The afternoon was devoted chiefly to the papers upon

SANITARY ORGANIZATION AND LEGISLATION,

by health officers, and the introduction of various resolutions. These latter referred to the prevention of blindness by Credé's method, the establishment of a National Board of Health and the Pasteur monument. This last provoked a most amusing little ebullition from Dr. Gihon, who moved first that each member who contributed to the secretary $1 for the Pasteur fund, be called upon for $10 toward the Rush monument fund of lingering fame. This being declared out of order, he promptly begged to amend the original motion by simply substituting "Benjamin Rush" for "Louis Pasteur," all of which were referred to the Committee of Resolutions.

THURSDAY, SEPTEMBER 17TH.

After one or two papers and reports upon the protection of rivers and other sources of water supply, WYATT JOHNSON, M.D., of Montreal, read a most interesting paper upon

THE SERUM TEST FOR TYPHOID FEVER.

It has been known for some time that the addition of a few drops of the blood-serum of a convalescent from typhoid fever to a pure, fresh culture of Eberth's bacillus, would produce a decided effect upon the organisms. It is now found that the blood of cases in comparatively early stages of the disease has the same power, and Dr. Johnson discovered that it still retains this potency even when dried, so that a drop of serum pressed out and allowed to dry upon a visiting card or scrap of paper can furnish a valuable diagnostic test. Specimens of cultures to which dried typhoid serum had been added, were shown alongside of others which had not been treated, and the contrast between the active and incessantly moving bacilli of the latter, and the motionless, matted and coagulated-looking germs of the former, was most striking.

A paper upon

THE PROPHYLAXIS OF TYPHOID,

was read by DR. ELIOT WOODBRIDGE of Ohio, but inasmuch as all references to treatment had been ruled out of it by the Sifting Committee according to the by-laws, as the author took pains to explain in his introductory remarks it was like "the play of Hamlet with the part of Hamlet omitted," and elicited no discussion.

Three very suggestive papers came next upon

THE USE OF FORMALDEHYDE AS A DISINFECTANT,

by PROFESSOR FRANKLIN C. ROBINSON of Bowdoin, and DRS. J. J. KINYOUN and E. A. DE SCHWEINITZ of Washington. A lamp for its generation was exhibited by the last-named, and all papers cited remarkable instances of its penetrating and sterilizing powers. In one experiment, infectious matter was introduced into the filling of mattresses, also smeared upon their surface and lightly rolled up inside them, and in both cases complete sterilization was effected by a comparatively short "charging" of the room with the vapor. It certainly seems as if this agent bid fair to become the chief reliance n house and car disinfection.

At the public session, in the evening, no little interest was excited by DR. ALBERT L. GIHON'S paper upon

THE BICYCLE IN ITS SANITARY ASPECTS.

It was a picturesque and dramatic arraignment of the wheel for its evil effects upon both sexes: upon men by humping the back, cramping the chest, and straining the heart, and upon women by throwing the weight of the body upon the perineum. The writer viewed with concern the prevalence of "scorching," and the idiotic attitudes necessitated by it, which, in his opinion, caused the vast majority of those who rode to receive more injury than benefit from the exercise. In the gentler sex he deplored first of all "the amazing revelations, for which bicycle costumes and their involuntary displays are responsible, of spindle-shanks, knock-knees, and less objectionable bow-legs," which "the machine" simply inflicts upon a suffering public without doing anything effective to remedy. On behalf of the esthetic sensibilities of the community he solemnly warned "the attenuated maiden" that "leather leggings and thick stockings only make her lack of symmetry more conspicuous," and the "stout matron, for whom no anatomical seat can be wide enough," that her "too-well-delineated outlines look much better when decorously veiled by a skirt." The day, he hoped, would soon come when "all women will realize that the spectacle of clumsily clad legs, working up and down like piston-rods, is not attractive to others, and is, after a while, monotonous and wearisome to themselves." Besides which it is unhealthy, because the horn of the saddle presses upon the perineum and threatens the welfare of generations yet unborn. The narrow saddle, with its hard horn, supports the woman bicyclist "as upon the point of a wedge," and, by its local injurious effects, far overbalances any value as exercise possessed by the wheel.

The discussion was opened by DR. ELIZA MOSHER of Ann Arbor, Mich., who, from the standpoint of a practising gynecologist, vigorously attacked Dr. Gihon's position and disputed most of his assertions. Intemperance is, of course, injurious here as elsewhere, but in her experience the vast majority of women riders were benefited in every way physically by the use of the wheel. The mysterious evils spoken of by Dr. Gihon might occur, but she had never met with a single case as yet, and on the other hand, had seen "woman after woman and girl after girl, by riding a bicycle, recover from maladies of which I had been unable to cure her before." As a means of healthful, vigorous exercise, an emancipator from the tyranny of dress, and an exhilarating relief from worry and nerve-strain, the bicycle had no equal.

The report of the committee on Alcoholic Drinks was a most refreshing piece of manly, scientific frankness. It boldly declared that the confusing and inclusion of the moderate drinker with the habitual drunkard, *à la* Murphy, was extremely harmful, and that the promotion of the regular dietetic use of vinous and light malt liquors was the best means of combating drunkenness. As the most practical remedies for the abuse of alcohol the committee recommended the increase of taxation upon distilled liquors, its removal or great diminution upon light wines, beer, cider, etc., a sanitary inspection of all drinks

sold over bars, and the encouragement of good wine-culture and good wine-making. The report closed with the ringing declaration: "Temperance is to be recommended rather than prohibition. We are heartily in favor of temperance or moderate drinking, and are as heartily opposed to prohibition." The remainder of the evening was devoted to consideration of the management of public baths.

FRIDAY MORNING, SEPTEMBER 18TH.

The last session of the Association was called to order by President Liceaga with an almost undiminished number of delegates in attendance. A considerable amount of unfinished and executive business was disposed of before a sudden and somewhat unexpected interest was developed by the report of the Advisory Council recommending Toronto as the next place of meeting. This seemed to cause such difference of opinion in the meeting that a vote was called for, and Nashville and Philadelphia both having been placed in nomination, a large majority of the delegates were found to prefer the latter city, which, accordingly, was decided upon. Dr. H. B. Horlbeck of Charleston, S. C., was elected president for the coming year; Dr. Peter Bryce of Toronto, first vice-president, and Dr. Ernest Wende of Buffalo, second vice-president.

JOSÉ RAMIREZ, M.D., of Yucatan, presented an abstract of a valuable paper

ON STATISTICS OF VACCINATION AND MORTALITY FROM SMALLPOX IN THE CITY OF MEXICO.

There has been, fortunately, practically no popular opposition to vaccination in the Sister Republic, and as it has been compulsory since 1891, nearly every individual in the City of Mexico has been protected by its performance. The result has been that, whereas smallpox used to form quite an important factor in the death-rate within recent years, it has now practically ceased to figure in the returns. Deaths from it are rare and usually occur in foreigners or recent arrivals from other States who have not been vaccinated.

A. N. BELL, M.D., of New York, followed with a brief but pointed paper upon

DRUNKENNESS, A VICE; IT SHOULD BE SO TREATED.

He took the ground that neither heredity nor disease had much to do with the causation of drunkenness. Inherited appetite for liquor was usually proved by finding one or more drunkards among the patient's ancestors or family. These could be found readily in almost every family (not even excluding the families of those present), if the search were pushed far enough. It may become a disease by neglect and repeated indulgence, and of course give rise to diseased conditions, but primarily it is a vice and not a disease. He pointed out that drunkenness is regularly associated with and leads to crime, pauperism, vice, and every form of moral degradation rather than physical. Drunkenness should be made a misdemeanor with increasing punishments, while the habitual drunkard should be first deprived of civil rights, and finally, if he persisted, confined in an appropriate institution, permanently or till such time as he gave good evidence of reformation, on the plan, in fact, of the "indeterminate sentence," as now applied to other habitual criminals.

Other papers were read, among them: "On the Prophylaxis of Scurvy by Pulque," by Francisco M. Baca, M.D., Puebla, Mex.; "The Relation of Noises to Public Health," by W. C. Krauss, M.D., of Buffalo; one which was not inappropriately titled "The Protection of the Innocent from Gonorrhea," by Ferd. C. Valentine, M.D. of New York (by "deep injection" methods that alone are sure to cure in ten days); and lastly on "The Necessity of Isolating Beds in Hospitals by Means of Windows Between Them," by Jesus E. Monjarás, M.D., of San Luis Potosi, Mex., but owing to the crowded program and nearness of the hour of adjournment, little discussion was possible. The one fault of the entire meeting was the attempt to discuss too large a number of papers at each session, from eight to fourteen being listed for every sitting, so that many of them had to be read by title or abstract and the discussions badly crippled. After an eloquent address in Spanish by President Liceaga, translated by his son, the Association adjourned to meet in Philadelphia next October.

SECOND INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS.

Held at Geneva, Switzerland, from August 31 to September 5, 1896.

THE address of welcome was made by Dr. Bétrix, who announced that representatives were present from France, Great Britain, Italy, Belgium, Spain, Sweden, the United States of America, Argentine Republic, and Switzerland. M. Lachenal, the Swiss President, dwelt on the great advances recently made in the diseases of women. Professor Runcin referred to the loss sustained by the Congress through the death of M. Vultict.

At the session of September 1st DR. G. BOUILLY of Paris, spoke on

THE TREATMENT OF PELVIC SUPPURATIONS.

Upon the knowledge of the exact cause of pelvic suppuration must rest the choice of the method of treatment. Considered surgically, pelvic abscesses may be divided into four classes:

(1) Abscess of the cellular tissue, parametritis. (2) Abscess of the tubes or ovaries, pyosalpingitis and suppurative oöphoritis. (3) Peritoneal abscess, pelvic peritonitis, suppurative hematocele. (4) Complicated abscesses, involving more than one organ, and possibly with sinuses leading to the skin or elsewhere.

Rejecting puncture as to-day unworthy of consideration, except as a means of diagnosis, the three methods of treatment are:

(1) Incision and drainage, abdominal or vaginal; (2) Exposure or removal of suppurating pockets by laparotomy, or (3) By the vagina, including hysterectomy, with or without morcellement of the uterus: (*a*) Removal of small unilateral collections per vaginam, without hysterectomy; (*b*) Removal by laparotomy of uterus and adnexæ.

Simple incision, with drainage, is the method of choice, and is applicable in acute abscesses, whether cellular or

peritoneal in origin, such as post-puerperal, or gonorrheal, or following operation, or in suppurative hematoceles. Thanks to better vaginal asepsis, and especially better drainage, incision and drainage are also applicable to many cases of encysted abscesses from the adnexæ. This treatment is most successful if the sac is unilateral, thin-walled, and situated low down. This simple operation give more cures than one would at first believe, and if it fail, a persisting sinus does not complicate a possible later vaginal hysterectomy.

Laparotomy and vaginal hysterectomy are not rival operations in the treatment of pelvic suppuration; each has its indications. If the lesion is surely or probably unilateral, especially in a young woman, laparotomy, as affording an opportunity for inspection of the adnexæ, is the operation of choice. This consideration is less strongly urged when there is a probability of the suppurative nature of the trouble than in case of cysts, etc., as suppuration is likely to affect both sides. In case of bilateral lesions, the situation of the purulent sacs, with reference to the uterus and vaginal vault, is important in determining the choice of operation. With these restrictions, vaginal hysterectomy can accomplish all that laparotomy can, and in some cases, by the former operation, conditions can be reached and cured that could not be reached by laparotomy without great danger. In abscesses separated from the peritoneal cavity by dense fibrous tissue, or in chronic abscesses with or without fistulæ, whose removal would be difficult or impossible, the removal of the uterus per vaginam is an operation relatively simple, and good drainage is thus secured. To attempt, in these cases, the enucleation of the abscesses is unnecessarily to increase the risk to the patient.

The operative results obtained by laparotomy ought not to be held to be proof of the superiority of that operation, as the recent figures of vaginal hysterectomy are much better than the former ones, and the cases subjected to laparotomy are simpler than those in which vaginal hysterectomy is performed. The immediate recovery from the latter is more rapid and the ultimate results are better.

In conclusion, in the large majority of cases in which incision and drainage are insufficient, vaginal hysterectomy represents the method *par excellence* of treatment of pelvic suppuration, and only when it is contraindicated is laparotomy in order.

DR. HOWARD KELLY of Baltimore, said that vaginal puncture ought to be attempted before recourse is had to laparotomy in the following cases:

(1) When there are compact inflammatory pus-cavities at the sides of or behind the uterus, in close contact with the vagina and separated by adhesions from the peritoneal cavity; (2) in old cases, in which a fistula exists opening into the rectum or bladder, or through the abdominal wall; (3) in cases of large hydrosalpinx easily accessible per vaginam; (4) for encysted pelvic peritonitis.

In such cases this operation presents the following advantages: (1) It is not followed by nervous troubles, as is the case after hystero-salpingo-oöphorectomy; (2) the functions of menstruation and conception are preserved; (3) rapid recovery—eight to ten days; (4) no danger of wounding the intestine, as may occur during difficult pelvic enucleation; (5) mortality less than two per cent.

Its dangers are: (1) Hemorrhage; (2) perforation of the rectum or the intestine (two cases); (3) penetration of the peritoneal cavity and death from infection (one case).

The following conditions will prevent complete recovery: (1) The presence of cellulitis extending to the pelvic walls and compressing the nerves and vessels; (2) contraction of the rectum due to the presence of perirectal inflammatory tissue; such tissue will persist and cause post-operative troubles.

In some cases exploratory incision will be necessary: (1) To determine the exact condition and the necessity for radical operation; (2) to avoid puncture of the intestine if lying between the abscess cavity and the vaginal wall; (3) to facilitate complete evacuation of the pus or to guide the instrument into old pockets.

Vaginal puncture is indicated especially in young married women and girls, upon whom a radical operation ought not to be performed until conservative treatment has been exhausted.

If an exploratory incision is made, the hands which make the incision and the examination through the wound, should not be used in the vaginal part of the operation. The steps of the procedure would then come in the following order: (1) Disinfection of the vagina; (2) selection of the spot most favorable for puncture, avoiding arteries, ureters, and bladder; (3) introduction of the finger or the scissors into the abscess cavity and enlargement of the opening; (4) the use, if necessary, of large uterine dilators; (5) lavage of the abscess cavity with normal salt solution, if there is no reason to suspect a communication with the abdominal cavity; (6) drainage by gauze, rubber tube, or silver cannula.

Conservative operative treatment would consist of (1) separation of adherent purulent tubes from the vagina and their puncture; (2) removal of the tube or ovary of one side.

The indications for salpingo-oöphorectomy, either simple or including one horn of the uterus, are: (1) Simple pyosalpinx. (2) Simple pyosalpinx with an isolated purulent focus in the uterine horn.

The indications for hysterosalpingo-oöphorectomy are: (1) Double simple pyosalpinx inaccessible to vaginal puncture. (2) Double adherent pyosalpinx, accompanied by purulent metritis and endometritis. (3) Pelvic abscess accompanied by appendicitis. (4) Pelvic abscess complicated by adhesions, comprising the small intestines. (5) Pelvic abscess with fistulous tract opening into the sigmoid flexure or the small intestine. (6) Pelvic abscess accompanied with myomata.

The method of performing hysterosalpingo-oöphorectomy by operating from left to right, or vice versa, presents the following advantages: (1) Great facility. (2) Easy recognition of the state of the lesions. (3) Easy removal of the tumors because they are attacked at the side where they are least adherent. (4) The vessels are easily clamped. (5) Abdominal drainage is unnecessary. (6)

Avoidance of post-operative residues, adhesions, intestinal obstruction, peritonitis.

In order to drain through the uterine pedicle the cervical canal is dilated, and the gauze is introduced from the abdomen through the cervix into the vagina. The peritoneum is sutured above the uterine pedicle.

Dr. Sanger of Leipzig, gave the following principles as governing German gynecologists in cases of pelvic suppurations:

(1) Indications must be most serious before an operation is resorted to. (2) The operation should be the most simple possible. (3) One must always choose the most appropriate operation for the given case in relying for that on the clinical, anatomical, and bacteriological diagnosis.

The greater number of gynecologists reject vaginal hysterectomy in cases of frequent pelvic suppurations; they prefer, as a rule, to operate by the abdomen.

The puncture is limited to the cases of encapsulated abscesses or to purulent collections in closed organs. One cannot hope for success unless the pus is sterile. In this manner one must treat only those cases where the purulent collection can be reached without crossing the cavity of the pelvis.

The incision is indicated in intraperitoneal or extraperitoneal purulent collections.

The incision is nearly always the preferred operation in chronic or single purulent collections where the pus is sterile. The incision is also indicated in certain acute cases, such as suppurations in Douglas' cul-de-sac.

Celiotomy is always indicated in case of purulent collections which form by their dimensions a real tumor. Celiotomy and drainage are all that are necessary in the case of encapsulated foci, unless the annexes and other organs are diseased and must be removed.

All suppurated organs must be entirely removed.

The indications for drainage are: (1) When virulent pus has contaminated the hand of the operator or an intact part of the abdomen. (2) When hemostasis is not perfect or there may have been at the same time a discharge of pus. (3) When there is a fistula or a perforation of the intestines.

The drainage (abdomino-vaginal) with gauze does not guarantee either the perfect flow of the secretions or the isolation of the rest of the abdominal cavity, unless a peritoneal band may have been formed above.

Dr. Richelot of Paris, said that it is not possible to decide exclusively for any one of the three methods; that each had its advantages.

The direct vaginal incision, the oldest method, is conservative, and more easily performed than a hysterectomy, but it is not adapted to all cases. It does not always succeed. Often a focus of suppuration is left behind when the puncture has healed, and this may give rise to new infection, a new abscess, and a return of all the trouble which it was intended to relieve. It is especially indicated in recent cases, and in *post-partum* suppuration, when, owing to the great friability of the tissues, extirpation is especially dangerous.

Laparotomy, though immediately successful, often fails in that it leaves in the pelvis, a congested, painful, and often infected uterus, which may render necessary a secondary hysterectomy. Its true field is where there are organs to be preserved. The age of the patient and the certainty, or the hope of a unilateral lesion, are also to be considered.

Vaginal hysterectomy in his hands has given a mortality of only 4½ per cent. in 569 cases. After the removal of the uterus, the tubes and ovaries give much less trouble than the presence of the uterus when they have been removed.

The popularity of vaginal hysterectomy rests on the use of clamps. It is no disgrace to use a great many, and he never introduces the tamponade as long as there is a drop of blood.

Dr. Hartmann of Paris, called attention to the fact that many patients are cured by medical treatment. It is therefore wise in all cases before operation to see what can be accomplished by rest in bed and vaginal antisepsis. Intrauterine treatment, dilatation, and curetting, are sometimes successful, but never in cases in which there are large circumscribed collections.

Dr. Henrotin of Chicago, emphasized the importance of an incision into the posterior cul-de-sac with the first sign of genital infection. By this means one obtains often only a slight serous discharge, which becomes purulent only after some days. The finger is introduced and exudates, if found, are broken up. If there is a very extensive exudate, an opening is also made in the anterior fornix. This early treatment prevents more serious trouble, and is far superior to curetting the uterus, which has been known to hasten the spread of the infection.

Dr. Sabino Coelho of Lisbon, has operated upon twelve patients by an incision through the anterior vaginal vault, as recommended by Martin. Pyosalpinx existed in nine cases, suppurative oöphoritis in the other three. The tumors ranged in size from a mandarin to an orange. All the operations were made without any accident, and the speaker holds that in unilateral cases this operation is preferable to hysterectomy, as it leaves the woman still capable of conception, and is preferable to laparotomy as it avoids the abdominal scar and its dangers.

Dr. Reynier of Paris, thought that there was danger in leaving behind inflamed adnexæ. These often give rise to troubles requiring further operation. Of the two, he was inclined to think contrary to Segond, that the remaining adnexæ were more troublesome than the remaining isolated uterus. He is in favor of laparotomy, which enables the operator to see what he is doing, and to make a clean operation by the removal of all diseased tissue.

Dr. Larozenne of Lyons has tried to make an incision stopping four or five centimeters from the pubis. He rarely has hernias by his method.

Dr. Quérel of Marsailles, practises buried suture, closing the peritoneum with catgut. The muscles and aponeurosis are reunited by braided silk. For large hernias he inserts a layer of calcified bone between the aponeurosis and the muscle.

Dr. Condamin of Lyons, practises the lacing suture for large hernias and umbilical hernias.

(To be continued.)

ANNOUNCEMENT.

ANTITOXIN COLLECTIVE INVESTIGATION (SECOND) AMERICAN PEDIATRIC SOCIETY.

To the Profession:

The American Pediatric Society are encouraged to ask the coöperation of the profession in a further collective investigation. Laryngeal diphtheria is believed to furnish a crucial test for antitoxin; the present aim is to ascertain (1) what percentage of cases of laryngeal diphtheria recover without operation, under antitoxin treatment; (2) what percentage of operative cases recover.

The Socie y asks for records of cases of *diphtheria involving the larynx, whether operated upon or not, occurring in private practice in the United States and Canada, treated with antitoxin.* It is expected that cases occurring this year will probably be treated with reliable preparations of the serum, will be treated early, and will be given efficient doses. In order to secure data which shall make the tables complete, circulars containing blanks for ten cases have been printed, and are now ready for distribution. It is desired that physicians shall fill out the circulars as cases occur, not trusting to memory, and shall urge their friends having similar cases, to report them. Circulars can be had by applying to the committee (address below). Several groups of cases in the first investigation arrived too late and were lost to the report. It is desired that circulars as soon as filled (ten cases) be returned to the committtee. The collection of cases must close at the end of March, 1897. The second report is designed to be a study of cases occurring between the closing of the first report, May 1, 1896, and the closing of the present collective investigation, April 1, 1897.

For extra circulars (blanks), for returning circulars (filled), and for further information please address the chairman of the committee:

W. P. NORTHRUP, M.D.

No. 57 EAST SEVENTY-NINTH STREET,
NEW YORK, October 1, 1896.

[To secure as great uniformity as possible in the treatment, the following suggestions are offered as they appeared in the resolutions of the Pediatric Society on accepting the first report:

1. *Dosage.*—For a child over two years old, the dosage of antitoxin should be, in all laryngeal cases with stenosis, and in all other severe cases, 1500 to 2000 units for the first injection, to be repeated in from eighteen to twenty-four hours if there is no improvement; a third dose after a similar interval, if necessary. For severe cases in children under two years, and for mild cases over that age, the initial dose should be 1000 units, to be repeated as above if necessary; a second dose is not usually required. The dosage should always be estimated in antitoxin units, and not of the amount of serum.

2. *Quality of Antitoxin.*—The most concentrated strength of an absolutely reliable preparation.

3. *Time of Administration.*—Antitoxin should be administered as early as possible on a clinical diagnosis, not waiting for a bacteriological culture. However late the first observation is made, an injection should be given, unless the progress of the case is favorable and satisfactory.]

REVIEWS.

SYSTEM OF SURGERY. Edited by FREDERIC S. DENNIS, M.D., Professor of the Principles and Practice of Surgery, Bellevue Hospital Medical College, etc., etc., assisted by JOHN S. BILLINGS, M.D., LL.D.Edin. and Harv.; D.C.L. Oxon.; Deputy Surgeon-General U. S. A. Vol. IV. Tumors—Hernia—Surgery of the Alimentary Canal—Appendicitis—Surgery of the Liver and Biliary Passages, of the Uterus, of the Ovaries and Tubes — Gynecological Surgery — Symphysiotomy — Surgery of the Thyroid—Surgical Peculiarities of the Negro—Surgery of the Female Breast—Use of the Röntgen Rays in Surgery. Profusely Illustrated, 8 vol.; pp. 970. New York and Philadelphia: Lea Brothers & Co.; 1896.

As may appear from the list of authors concerned in its preparation, this final volume maintains the standard of its predecessors in the series. Among the subjects discussed in it are some in which the most conspicuous of the advances of modern surgery have been made.

It opens with an article on tumors, by the editor. This, which occupies one hundred pages, is supplemented by a brief essay on the microscopic appearances of these structures, from the pen of Dr. E. K. Dunham. The nomenclature and classification of new growths here given is credited to Dr. J. W. S. Gouley. It does not differ materially from that recently proposed by Sutton, but seems to us to be needlessly complicated by the multiplication of terms and subdivisions. With regard to treatment, space is deservedly given to the discussion of Coley's method of dealing with inoperable cases by the injection of mixed toxins. Some of the reported results are so striking as to suggest the idea that further experience may lead to an extension of this procedure to some of the cases now regarded as amenable to operation.

Abdominal surgery next comes under consideration, in a series of articles by well-known authors. Hernia is discussed by Drs. Bull and Coley of New York. The surgery of the alimentary canal, from the pharynx to the ileocecal junction, has been assigned to Dr. M. H. Richardson of Boston, who has had the assistance of Dr. Farrar Cobb of the same city. Appendicitis is made the subject of two articles, the first by Dr. Hartley of New York, on the clinical and pathological features of the disease, the second, by Dr. McBurney, on its surgical treatment. A chapter on the surgery of the large intestine is contributed by Dr. L. S. Pilcher of Brooklyn, and one on that of the liver and biliary passages by Dr. Robert Abbe of New York.

The four following chapters are upon gynecological topics. Dr. William M. Polk of New York, takes up the surgical disorders and diseases of the uterus, Dr. Joseph Taber Johnson of Washington, D. C., those of the ovaries and tubes. Minor gynecological surgery is set forth by

Dr. H. C. Coe of New York; while a separate article by Dr. W. T. Lusk of New York, is devoted to symphysiotomy.

The surgery of the thyroid gland is the subject of a special chapter by Drs. R. F. Weir and E. M. Foote of New York; and this is followed by a discussion of the surgical peculiarities of the negro, by Dr. Rudolph Matas of New Orleans. Further study in this direction, and a comparison of the varying features and susceptibilities of different races, would seem to be invited by the opportunities for such investigation afforded in several of the great cities of the country.

The subject of diseases of the breast is treated by the editor himself. The volume concludes with a brief sketch, by Dr. W. W. Keen of Philadelphia, of skiagraphy by means of the Röntgen or X-rays.

All the articles now enumerated are the work of men of reading, observation, and experience, and are fully "up to date." With their teachings we have no fault to find; but we think the student, and perhaps the average practitioner, will sometimes wish that they had been written on a lower plane, or at least with more of elementary detail. For instance, the article on the X-rays opens with the statement that pictures were taken "by means of certain rays emanating from a Crookes' vacuum tube." But unless the reader happens to know what a Crookes' vacuum tube is, and how rays are made to emanate from it, and how "certain rays" differ from other rays emanating from it, the whole matter still remains as Cicero's speech was to Casca, Greek to him.

Abundant evidence is afforded throughout this volume of the familiarity of the authors with foreign, and especially with German, literature. We cannot but note with regret that they seem to have found in the writings and labors of their fellow countrymen almost nothing worthy of citation or reference.

The mechanical execution of this book is highly creditable, and the illustrations are, for the most part, exceptionally fine.

A Treatise on Appendicitis. By John B. Deaver, M.D. Philadelphia: P. Blakiston & Co. Pp. 164.

The author of this treatise states in the preface that the work "has been prompted by the belief that the importance of this affection entitles it to a more thorough and exhaustive study than has usually heretofore been accorded it." This is to be construed into a promise to the purchaser of the book that it shall contain something which has not appeared heretofore, and that, with this in view, a "more thorough and exhaustive study" will be given to the subject than has been given by previous writers. No one will question the importance of the affection, and in view of this, a promise based upon such a statement of fact becomes a most solemn obligation. The expectation of the reader is still further enhanced by the assertion, duly set forth, that "the observations herein contained are the result of an experience in the treatment of over five hundred cases." The concluding sentence of the book, however, shows that these were all operative cases, and it is therefore fair to assume that the experience of the author is confined to the operative treatment of the disease.

He who seeks for something new in the author's presentation of the subject will be disappointed. The chapter upon "History" is largely a compilation from Talamon's "Appendicite et Périty phlite," published in 1892, and the more recent work of Hawkins upon the "Diseases of the Vermiform Appendix" (1895).

In the chapter upon "Etiology," the usually recognized causes of the disease are given, but no new light is thrown upon the subject. He follows Talamon in the belief that acute indigestion plays a very important rôle in the etiology of appendicitis, and, while admitting that seeds and other foreign bodies have been found in the appendix, contends, with most recent writers, that, in the large majority of cases, the supposed seeds were fecal concretions.

In the chapter upon "Pathology," the four stages given by Fowler are followed. The lessened vitality and anatomic peculiarities of the organ are acknowledged to be reasons for the more frequent invasion of the appendix by microörganisms, as compared with other portions of the intestinal tract. In the present state of our knowledge upon the subject, the statement that "the most important determining cause of an invasion by the microörganisms is the existing virulence of the colon bacillus," is scarcely warranted.

Twenty-seven pages are devoted to the subject of diagnosis. Issue might be taken with the author upon the accuracy of the statement contained in the opening paragraph of the chapter, to wit, "When the three cardinal symptoms, viz., sudden onset of acute abdominal pain, with or without vomiting, occurring in one previously well; unilateral rigidity of the lower abdominal wall; tenderness over the site of the appendix—the diagnosis of appendicitis is *unexceptionally* warranted." (Italics ours). This statement fails to take into account the possibilities of a ruptured right tubal pregnancy, rupture of a right pyosalpinx in a patient with few or no previous symptoms, and twisting of the pedicle of a small right-sided ovarian cystoma, to say nothing of acute intestinal obstruction in the neighborhood of the ileocecal valve, all of which, while they fully justify the operator in opening the abdomen, may lead to diagnostic error if only the three symptoms mentioned are taken into account.

The statement made by an eminent medical authority that ninety-five per cent. recover without operation, is undoubtedly based upon insufficient diagnostic data, and is none too vigorously opposed by the author. While it is probably true that there is a certain and definite proportion of cases which recover without operation, it is also true, as stated by our author, that "it is impossible to foretell what will be the outcome of any attack."

In the matter of treatment, the author states that "my observation has forced me to the conclusion that there is but one course to pursue in order to obtain the best possible results, viz., to remove the appendix as soon as the diagnosis has been made." Without doubt many medical practitioners will object to this, and will back up their objection by the recital of cases which have recovered without operation.

It is probably true that much may be said upon both sides of the question when the line is as closely drawn as our author draws it, and it is not too much to say that indiscriminate opening of the abdomen at the hands of incompetent operators may be responsible for as many deaths as over-conservatism in the expectant treatment of appendicitis.

Many of the plates are placed in the book without reference to the relevancy of the accompanying text, and have facing them pages occupied entirely by the history of cases, instead of matter descriptive of the plates.

The general mechanical makeup of the book is such as to reflect credit upon the publishing firm whose name appears upon the title page.

DIE KRANKHEITEN DER WARMEN LANDER. Ein Handbuch für Aerzte, von DR. B. SCHEUBE. Jena, 1896. Verlag von Gustav Fischer.

[Tropical Diseases. A Handbook for Physicians, by Dr. B. Scheube. Published by Gustav Fischer. Jena, 1896].

THE author of this book is already well-known to the medical profession through his writings on beriberi; the most authoritative in existence. He was formerly professor in the medical school at Kioto, and his training and experience entitle him to speak positively on tropical diseases. We have no hesitation in saying that this book surpasses every one dealing with the same subject that has come to our notice. The 450 pages comprise five chapters which deal respectively with, (1) general infectious diseases; (2) intoxication diseases; (3) diseases caused by animal parasites; (4) organic diseases, and (5) unclassified diseases. The first and fourth parts will be found most interesting and instructive to physicians of the Occident and temperate climates, although one cannot read any of the other chapters without enlarging his medical knowledge and modifying his point of view. Under the general infectious diseases detailed and elaborate descriptions are given; among others of bubo-pest, an infectious disease of great acuteness and severity, characterized by inflammation of the glands, development of carbuncles, great pyrexia, and profound prostration; dengue fever; yellow fever; Mediterranean or Neapolitan fever; malaria of the tropics; beriberi, and lepra arabum. Each of these are discussed in the completest way; first the name, the natural history, and geographical distribution; the etiology; the clinical picture, or symptom-complex and its variations; the diagnosis, differential diagnosis, and prognosis; the pathological anatomy, and, finally, the therapy. And under the latter the prophylaxis, as it deserves, receives detailed consideration. In fact, one of the most valuable features of the work, and one that cannot fail to be attended with material benefit, is the prominence given to discussion of prophylactic measures. In no part of the book is this more apparent than in the discussion of beriberi and malaria, two diseases almost completely preventable, which are, at least, robbed of their malignancy by the observance of general and personal hygienic measures. The etiology of malarial fevers is handled in a most masterful manner; the various parasites—the quartan, the tertian, the quotidian, the malignant tertian, the half moon-shaped of Laveran, the *corpora flagella* or polymitous form—are all taken up in detail, and their claims for preëminency as causative factors carefully weighed.

The chapter on beriberi is sufficiently referred to when we say that it is in reality a digest of the author's book on that form of epidemic multiple neuritis, to which the name beriberi is given. His description must remain a standard from a clinical standpoint for all time, and from a pathological standpoint until the bacteriological investigation reveals the real causes of the disease.

In the chapter on intoxication diseases pellagra is described.

The least satisfactory chapters in the book, and the ones that do not materially advance our knowledge of the diseases considered, either from a historical or from a clinico-pathological point of view, are those devoted to sleeping sickness of the negro, amok, and latah. These are evidently included, not that the author has anything new or critical to say about them, in fact his statements anent these are almost entirely based on the observations of others, but that he may insure completeness. Considered as such, they fulfil their purpose.

In a brief notice the merits of a book, like the one under consideration, receives but inadequate mention, but when we say that, in our opinion, it contributes to the illumination of some of the most destructive and obscure diseases which afflict mankind, we shall have sufficiently manifested our desire to speak well of it.

BLIND LEADERS OF THE BLIND. A Novel, by JAMES R. COCKE, M.D. Lee & Shepard, publishers. Boston.

THIS book has no *raison d'être* whatever—neither beauty of style, nor appeal to refined emotions and sentiments, nor yet the development of a consistent story is to be found within its pages. The book is a collection of incidents, very naïvely told, loosely strung together, and appealing to a love of the morbid and pathological. It would hardly be possible for us even to enumerate the number of murders, diseases, crimes against person and properties, not to speak of the absurd diagnoses and fulsome adulation, and advertisement of false prophets in hypnotism, in which the book abounds. The public cannot be instructed by this book; it needs to be warned against statements made with a show of special knowledge on the part of a physician who has written a work on hypnotism. He indicates the possibility of a blind man, who had been suffering total blindness from before his fifth year, seeing the sun, and the moon, with its shimmer upon the water at night, by means of a magnet and the touch of his loved one, as though directing his mental gaze hither and thither in unison with the movements of her eyes. Preposterous and ridiculous as this is, it is fraught with such danger to the unthinking and unprofessional reader that the publication of such a book by a physician can be regarded in no other way than reprehensible. Of the making of books there is no end. Fortunately we are not obliged to read them all.

LEUCOCYTOSIS AND IMMUNITY, WITH A CRITICAL ANALYSIS OF THE THEORY OF NUCLEIN-THERAPY.

BY WALTER A. WELLS, M.D.,
OF WASHINGTON, D. C.

THE establishment of a therapeutical system, founded upon nature's own process of protecting the living organism against disease, is one of the highest aims of scientific medicine. In the past few years, accordingly, there has been an extraordinary development in our knowledge of natural and acquired immunity. Should we ultimately realize the end of these researches, a mass of empirical formulæ will be replaced by rational and precise methods.

The theory of Asclepiades was a remarkable foreshadowing of modern cellular pathology. According to him, the body was made up of numberless atoms and pores, the disturbance of whose normal distribution and symmetry resulted in a departure from health.

But humoralism, set upon the march by Hippocrates and receiving afterward the indorsement of the great Galen, withstood all attacks, and remained paramount throughout the Middle Ages.

Virchow showed the great rôle the living cells play in the living organisms, and Metschnikoff would still farther elevate their importance and significance in the struggle of the organism against disease. But ancient humoralism again appears in the garb of modern serum-therapy.

Very recently there has been propounded by certain French authors a theory that resembles still more closely the old humoral doctrine. This is the so-called theory of "internal secretion," according to which the most diversified glands of the body contribute to the preparation of the blood, furnishing it, perhaps, with enzymes destined to neutralize poisons produced as a result of metabolic change. The secretions from any one gland, moreover, can compensate for the failure of any other.[1]

In 1892, there was waged, especially in England, a bitter warfare over phagocytism and its relation to immunity. Klein asserted that the cell constituted a retreat into which the microörganism entered to avoid the bactericidal influence of the fluids. German pathologists chiefly brought forward some powerful arguments deduced from experiments, to show that the lymph or serum possessed "antibiotic" properties.

Baumgarten[2] did most to discredit phagocytism in Germany, and brought the strongest proof to establish the serum doctrines. He claimed to have demonstrated by experiments that degeneration and disappearance of the bacilli occurred in the lymph-fluids. Buchner[3] contended that the blood-serum destroyed the bacteria, and that the leucocytes, acting as scavengers, afterward carried off the already devitalized microörganisms.

But almost immediately we began to hear that these two schools were not really irreconcilable. Sanarelli,[4] for example, in 1893, wrote:

> Le grande nombre d'arguments apportés par M. Metschnikoff et son école en faveur de cette théorie phagocytaire n'a pourtant pas empêché d'invoquer pour expliquer l'immunité vaccinale, d'autres conditions statiques consistant en des propriétés chemiques du sang et des humeurs, qui seraient en état de proteger à eux seuls l'organisme.

But Sanarelli, Massart, Werigo, Isaeff, continue to maintain that the essential factor in immunity is the phagocytic leucocyte, and deny the claim of Behring and Nissen, Foa and Carbonne, Emmerich and Fawitzky, Krouse and Pansini, that the blood of a protected animal is directly destructive of bacteria (bactericidal theory); as also the theory advocated chiefly by Charrin and Rogers, that the microörganisms were not destroyed in the serum, but only divested of their pathogenic properties (theory of attenuation); and likewise the contention of Behring and Kitasato, G. and F. Klemperer, Mosny, and more recently of a host of others, that the serum may *contain* a substance which neutralizes the toxins produced by the bacilli.

The phagocytic theory has recently been made the foundation of a new therapeutic system, the nuclein-therapy, which has a wide-spread popularity in this country. An agent, essentially the same as nuclein, had been employed by the enemies of phagocytosis, in order to combat this theory. There had been described by Wooldridge, in 1888, a new method of "chemical protection." He used a solution of what he called "tissue fibrinogen," which he prepared from the thymus and testicles of animals. Injecting this agent into

rabbits, he claimed that they were thereby rendered immune against subsequent inoculation of anthrax.

Harkin, an opponent of phagocytosis, made some study of this principle, and added the idea that it possessed bactericidal properties. Wright[8] followed closely the formula which Wooldridge had used in preparing his "fibrinogen," and studying the same chemically, demonstrated conclusively that this agent was of the nature of a nucleo-albumen or nucleo-protein. This statement was to an extent substantiated by the fact that fibrinogen introduced into the system produced leucocytosis, since there had just then been published Horbaczewski's[9] famous work, wherein it is shown that the effect of nuclein is to increase the number of white blood-corpuscles.

This property of nuclein, to cause a leucocytosis, is the fact to which the advocates of the nuclein-therapy now point as the proof of the curative powers of that agent. Upon the theory of phagocytosis it is plain, they tell us, that if you have an increase in the number of the leucocytes, the enemies of the bacteria, the system is better fortified against disease. The premises are as simple as could be wished. Let us therefore inquire thoroughly into them.

It is known that nuclein belongs to the albuminoids, a class nearly related to the proteids, in their percentage composition, in their colloid nature, and their considerable proportion of nitrogen. Nuclein is rich in phosphorus, soluble in weak alkalies, and precipitated by weak acids. True nuclein yields as a decomposition product xanthin bases, a fact first demonstrated by Kossel,[7] and is thus distinguished from the others, as para-nuclein.

Horbaczewski showed that the nuclein of spleen-pulp yielded in the presence of oxidizing agents uric acid. Administering nuclein, moreover, he obtained an increase of the uric acid in the urine of man. The uric acid thus excreted in excess of the normal was thought to be formed out of the white blood-corpuscles. Weinbrand,[8] however, has reached conclusions to the effect that the increased uric acid is in all probability formed from the xanthin bases of the nuclein, and does not depend upon a leucocytosis.

Accepting this view, we may ask whether the leucocytosis is not the result of the uric acid, for it is known that uric acid has the power to bring about such an effect. At the same time, another pertinent question is: Why may we not assume for those other agents which give rise to a leucocytosis the same therapeutical virtues that we assume for nuclein, since this action is the ground of its claims?

As long ago as 1856, Hirt[9] had seen an augmentation of the leucocytes follow the inhibition of certain "tonisirende mittel," especially tincture of myrrh.

In 1876, Binz[10] made similar observations as to ethereal oils, especially turpentine and camphor. Pohl[11] enlarged the list very materially in 1888, showing that a leucocytosis ranging from 25 to 125 per cent. was produced by the following substances: Subnitrate of bismuth, oxid of iron, acetic ether, oil of fennel, oil of cloves, oil of peppermint, tincture of myrrh, oil of turpentine, vanillin, musk, absinthe, quassia, gentian, piperin, and strychnin.

Cutler and Bradford[12] were the first to observe that the same effect followed the administration of phosphorus, cod-liver oil, and quinin. Leber[13] produced a leucocytosis by the use of phlogosin, and Haidenhain[14] had the same result with leech-extracts. That the phenomena of leucocytosis follow upon the introduction of bacterial cultures, bacterial extracts, and alkali proteins into the system, we know well enough from the experiments of Arloing,[15] Somer,[16] and many others.

Among other agents which will give rise to leucocytosis are the following: Peptone, hemialbumose, uric acid, nucleinic acid, urea, urate of soda, curare, pyrodin, chlorate of soda.

All these agents give rise to a polynuclear leucocytosis, only those white corpuscles with multiple nuclei and neutrophilic granulations being increased.

The earliest view of leucocytosis was that of Virchow, who believed it was the result of the stimulation of the lymphatic glands, these being the glands chiefly, whose function it was to produce the leucocytes. Stimulation caused increased activity in these glands, and consequently an immediate over-supply of the corpuscles.

Virchow's theory of new production was later adopted by Von Limbeck, who added, however, the principle of chemotaxis as complementary to its solution, holding that those substances introduced into the system, with the power to produce a leucocytosis, acted in virtue of certain chemotactic properties (which will be discussed later) to attract the leucocytes from the blood-making glands. Von Limbeck thought he had strengthened this theory by experiments, in which it was seen that the blood in the splenic vein contained more leucocytes than that in the splenic artery. The physiological fact cited by Ehrlich,[17] that the

blood-forming organs *sent forth into the circulation none but the mononuclear elements*, was most fatal to this doctrine. Such a fact, clearly, seemed not to permit the idea of new production, when it was known that the majority of the leucocytes in these experimentally induced leucocytoses was of the polynuclear class.

Further investigation showed that an inequality in the number of the leucocytes in the arteries and veins in favor of the latter was the usual condition. Römer's[18] theory was that a new formation of the white blood-corpuscles took place directly in the circulating blood. The substance introduced into the system and gaining entrance into the blood stimulated the corpuscles themselves, so that there resulted a division and new formation by the process of amitoses. Römer laid stress on the grouping of four to six cells, which he frequently observed in the slides of leucocytotic blood. But subsequent investigators attributed his grouping together of the leucocytes to the so-called "viscosity" (Virchow) of these elements, and the division-figures, which he claims to have so often seen, Schulz has affirmed to be merely the artificial lapping of one cell over another.

Löwitt,[19] who was the first to bring into special prominence the universally admitted fact that "the increase in the number of the leucocytes is always directly preceded by a decrease," believed this preliminary decrease of leucocytes to be the result of wholesale disintegration of those elements, and applied therefore the term "leucolysis." He distinguishes from leucolysis, "leucopenia," or a poverty of the blood in colorless corpuscles, due to a diminished supply from the blood-forming organs. The latter was distinguished not only on account of a different causation (as exposure to cold), and in its more gradual onset, but also in the fact that here the mononuclear elements, those which come directly from the hematopoietic organs, are the ones which are chiefly wanting, whereas in leucolysis, the decrease affects chiefly the polynuclear class. It is especially because of the diminution being in the mononuclear elements, that the author concludes that this leucopenia arises from a lessened supply, since, as he observes, there is no reason to suppose a one-sided destruction, which affects only that class. Yet a one-sided destruction affecting the polynuclear is what this author is obliged to assume in his hypothesis of leucolysis, and this to my mind is one of the weak points of his theory. His experiments were all upon rabbits.[20] Taking some blood from the cervical vein of this animal, he made the following count:

Whole number of leucocytes . .	13,824
Mononuclear, 52.4 per cent . .	7,243
Polynuclear, 47.6 per cent . .	6,581
Erythrocytes, 7,490,000.	
Ratio, 1–542.	

An injection of one gram peptone, made five minutes later, gave this result:

Whole number of leucocytes . .	3142
Mononuclear, 77 per cent. . .	2419
Polynuclear, 23 per cent. . .	723
Erythrocytes, 6,290,000.	
Ratio, 1–2002.	

In other instances the decrease is yet more striking on the side of the polynuclear forms. Löwitt has not himself ventured an explanation of this partiality of the destructive substance, but one of his followers, A. Schmidt, has suggested that the mononuclear cells, being the younger, are the more resistant. It seems to me more natural to infer just the reverse, and to regard the young, newly born elements as tenderer, and the ones likely to be earlier destroyed. In fact, observations on the warm stage tend to show that the polynuclear forms are indeed decidedly more active, exhibiting by far livelier and more pronounced emollient movement. All observers are agreed that the polynuclear leucocytes are preeminently the phagocytes of the blood.

As a result of his many experiments, Löwitt found that the sooner the blood was taken after the injection of an agent which gave rise to the phenomena in question, the more marked was the decrease of the leucocytes; and, moreover, the greater proportionately was the decrease of the polynuclear forms—all, of course, within the stage of leucopenia. He was able to prepare the blood for examination in five seconds after the injection.

Having first made a count with the following result:

Leucocytes	9143
Mononuclear, 64.2 per cent. . .	5869
Polynuclear, 35.8 per cent. . .	3274

he injected one gram hemialbumose into the veins. A count from the blood withdrawn *five seconds* after gave

Leucocytes	413
Polynuclear, 4.6 per cent. . .	19
Mononuclear, 95.4 per cent. . .	394

Löwitt interprets these facts thus: By the introduction of certain substances into the blood, there is brought about an *immediate* and complete destruction[21] of the leucocytes. The blood-making organs attempt forthwith to compensate for this total deprivation, and hence is accounted

for the early predominance of mononuclear elements. The few polynuclear forms to be seen at this time are due to the transformation which has taken place—in accordance with Uskow's generally accepted doctrine—from the mononuclear forms. The continuance of this process of transformation is the only way of accounting for the growing number of these, the polynuclear.

To accept Löwitt's explanation, we are obliged to assume premises which scarcely appear to me as probable, namely: That the hematopoietic organs could perceive the want and discharge, even into the most peripheral vessels, the white blood-corpuscles, and that, moreover, some of these, at least, passing through the intermediary stage (transition-forms), become perfectly matured polynuclear leucocytes, with neutrophilic granulations—all in the space of *five seconds.*

At the end of this period of leucolysis, Löwitt has observed, in common with other experimentors, that there begins a rise in the number of the white corpuscles, especially the polynuclear forms, which reaches its height in from five to seven hours after the introduction of the agent. But Löwitt is original in his interpretation of this augmentation, in that he holds "dass die Leucocytose Folge der vorausgegangenen Zerstörung von Leucocyten ist;" that, in other words, the leucolysis and leucocytosis stand in a relation to each other of cause and effect. Such a conclusion is the outcome of simple *post hoc ergo propter hoc* reasoning, the author being influenced by the invariability of the association.

Schulz[22] made certain experiments, from which he was led to believe that the decrease and increase in the blood, as shown by the count, was the result of an unlike distribution of the leucocytes. Having injected 2 cc. bacterial proteins into the right ear of a rabbit, and withdrawn the blood soon after from a vein of the other ear, the number, which previous to the injection he had found 11,100, had sunk to 3300 (stage of leucolysis?). As quickly as possible, with the help of an assistant, the blood from the internal organs was withdrawn for examination with these results: gastric vein, 21,000; renal vein, 20,000; portal vein, 27,000; hepatic vein, 18,000. There was an increase then over the normal, rather than a decrease, for the internal organs at the same time that the peripheral showed a diminution.

Experiments were also made by an English author, Bruce,[23] apparently unaware of those of Schulz, that yielded similar results, though, if anything, the inequality in the numbers of the peripheral organs was still more striking.

These experiments were accepted as conclusive by X. Rieder, than whom there exists no higher authority in hematology. He writes:[24]

> As to the origin of leucocytosis, we have upon the ground of experimental examinations no good reason to believe that it is due to an increased supply of white blood-corpuscles from the blood-making organs; still less to an increase of the same in the blood, or to an abnormal collection of wandering cells.
>
> It must be considered as more probable that the leucocytosis is based only upon an insignificant increase of the entire number of the white cells circulating in the blood, in that there occurs an abnormal distribution of the same in the different vessels, in favor of the periphery.

Among other authors who look upon an increase of the white blood-corpuscles as being not an absolute increase of the whole number, but having only a local significance we can mention Werigo,[25] Goldschier and Jacob,[26] Tschistowitsch[27] and R. F. Muller.[28]

Tschistowitsch, moreover, in order further to test the doctrine of Löwitt, made a number of varied experiments to discover whether those substances which were supposed to cause a leucolysis, would effect outside of the body a disintegration of the leucocytes, and his results were all upon the negative side. Goldschier and Jacob also made experiments that were opposed to the hypothesis of Löwitt. Among other things, they were able, by the injection of small and often repeated doses of certain substances, almost to avoid the stage of hypoleucocytosis,[29] and, nevertheless, they saw follow, upon the suspension of the injections, a very intense hyperleucocytosis.

All these authors then, though they differ among themselves, believe together that the increase of the leucocytes observed at one place is compensated for by a corresponding decrease elsewhere, and *vice versa.*

The above, it must be borne in mind, is not to be applied to that augmentation of leucocytes which occurs in leucocythemia (leucemia). Here there is a leucocytosis clearly of another kind than that artificially induced by various chemical agents, and the inflammatory and the cachectic leucocytosis, in that, instead of a predominance of the polynuclear forms seen in the last-mentioned instance, it is characterized by an excess of the mononuclear or young forms. For this reason, and because also we see in leucocythemia elements which are not to be found in normal blood, as Conneil's, Ehrlich's, and the eosinophilic myelocytes,[30] we are justified in considering the leucocytosis of this disease as really arising from a new production of elements. If this be true, we have, on account of this distinction, the more reason for regarding that other kind of leucocy-

tosis, where the neutrophilic polynuclear forms prevail, as not the result of a new production, but arising in some other way.

The question that we have now to consider then, is, what is the cause of the ordinary leucocytosis? If it be the consequence of an unequal distribution of the leucocytes, what is the determining influence?

According to my belief, the key to the whole problem is to be found in the principle known as chemotropismus, or more commonly as chemotaxis. This important principle was discovered by the botanists, Stahl and Pfeffer, in the cells of plants, where it was held by these authors to exercise an influence over cellular digestion and nutrition (therefore the term trophotropismus). Its application to the leucocytes, and especially the phagocytes, has been comprehensively studied by Massart,[31] Bordet,[32] and Gabritschewsky.[33]

Chemotaxis is a peculiar property inherent in the white corpuscles of the blood and the migratory cells, by virtue of which they are attracted toward certain chemical substances or repulsed by them; the phenomenon in the former case being designated positive, in the latter negative chemotaxis. Experiments undoubtedly show that a positive chemotaxis becomes a negative one, if the agent employed be applied in more highly concentrated state.

Römer and others early recognized that leucocytosis ought to be studied in connection with chemotaxis. But without question, the credit for the first clear statement of that connection is due to Rieder,[34] who, as long ago as 1887, at a session of the Academy of Sciences in Vienna, expressed himself in regard to the action of this principle in bringing about leucocytosis as follows:

> In the beginning, a great part of the leucocytes circulating in the blood are attracted toward the *locus læsionis*, so that a certain poverty of the circulating blood resulted; after an interval, the agent possessed of chemotactic properties—that is to say, attractive to the leucocytes—entered the blood, where it acted by virtue of those same attractive properties to cause a streaming hither of the leucocytes.

Other authors have placed a different construction on the operation of chemotaxis.

Weigert has spoken of intra- and extra-vascular chemotaxis. Goldschier and Jacob have ascribed the diminution preceding the leucocytosis to a withdrawal of the leucocytes into the capillaries.

R. F. Muller,[35] who made examinations as to this point, found in a number of instances that during the period in which there was a hypoleucocytosis in the blood as shown by the peripheral vessels, there was a veritable increase in the capillaries of the internal organs. The experiments of Borel[36] also went to show that under similar circumstances there was a marked engorgement in the capillaries of the internal organs, especially of the lungs.

The application of chemotaxis to leucocytosis was very readily accepted by the Metschnikoff school, for the existence of such a property in the leucocyte was an idea quite consistent with its phagocytic characteristics, and subservient to that function. According to the phagocytists, the poisons which entered the system collected first in the abdominal organs, lungs, liver, and spleen. The attraction of the leucocytes to these organs is, then, exactly what should be expected in order to exercise the phagocytic function. So Borel and others have seen, after injection of bacteria cultures, that many of the leucocytes collected in the internal organs contained in their interior those bacteria. One point, however, needs elucidation. Ought not we to expect that the leucocytes would, in the increase and the decrease, simply retain their normal proportion of both forms?

Only Rieder has in any way ventured an explanation on this point, in that he has remarked that perhaps the preponderance of the neutrophilic forms was due to the stagnation of the corpuscles in the vessels, where the process of maturing was allowed to proceed.

Is the explanation not, rather, to be sought in the difference in the nature of the young and the old leucocytes? The polynuclear leucocytes with neutrophilic granulations, being apparently possessed of characteristics which would lead us to expect they would the more quickly respond to chemotactic influences, and being, as hematologists assert, the forms (just as the amphophiles in the rabbit) which are intended by nature to war against germs or noxious agents, is it not natural to suppose, then, that the neutrophilic leucocytes would be those—chemotaxis being the force at work—to appear in the greatest number?

Hankin, having first added some leech-extract to a little blood in a vessel, in order to prevent coagulation, introduced a glass rod. In a little while the blood was almost free of leucocytes, but, withdrawing the rod, he found that it was covered with corpuscles to an extent perceptible to the unaided eye. He did not, however, attempt to differentiate the corpuscles.

In their studies of the action and character of the phagocyte, Everard, Demoor, and Massart[37] introduced small sacs, opened at one end and containing sterilized cultures of bacteria, into the

peritoneal cavity of animals. After some hours the sacs were withdrawn and the contents examined. The results were positive and invariable, in that the leucocytes were almost entirely of the polynuclear variety. The authors were evidently justified from such experiments in concluding that the "polynuclear leucocytes are by far more chemotactic than the others."

Thus is rendered complete the demonstration of the theory of the chemotactic origin of leucocytosis. We can as easily understand, in this light, the disappearance of the polynuclear leucocytes in the stage of hypoleucocytosis, as their reappearance in the stage of hyperleucocytosis; and the observation of Löwitt that the nearer the time of the introduction of the agent, the greater was both the diminution of all leucocytes and the proportion of polynuclear forms, is precisely what we should *a priori* expect, as the expression of greater chemotactic operation.

We must, then, set down leucocytosis as only a local condition, and those agents which give rise to a leucocytosis as agents which effect merely a determination of the white blood-corpuscles from one part of the system to another.

To return once more to the nuclein-therapy, wherein is its *rationale*, if the above view of leucocytosis be the correct one?

According to Prof. Vaughan, the chief advocate of this system of therapy, as well as his followers, if nuclein has any efficacy in the cure of tuberculosis, it is due to its power to augment the number of the white blood-corpuscles. Vaughan[38] concluded an article on "The Treatment of Tuberculosis by Yeast-nuclein" as follows:

> I am convinced, especially from my experiments on animals, that nucleinic acid, improperly used, may do harm. It acts, as I have elsewhere shown, by stimulating the organs that elaborate the polynuclear corpuscles, and these may be over-stimulated. Nucleinic acid fails to be of service unless these cell-forming organs respond. They may fail to respond on account of lowered vitality, or they may be paralyzed, as it were, by an excessive dose of stimulant. The agent is not one to be used indiscriminately. Already some physicians are supplying tubercular patients with hypodermic syringes and solutions of nucleinic acid and telling them to go ahead and treat themselves. Such practice as this may make the study of this subject result in misfortune.

As regards the observation of untoward effects proceeding from the administration of nucleinic acid, Vaughan is not alone, for Löwitt has stated that this agent proved in a "high degree poisonous" given to rabbits in amounts of 0.1 per cent. per kilo, causing quickly cardiac and respiratory failure. He is alone, however, so far as I know, in attributing to any organs of the body the function of elaborating the polynuclear leucocytes, for, as we have elsewhere remarked, modern authorities are agreed in looking upon the polynuclear cell as matured form of the mononuclear, which form of cell only is elaborated directly by the hematopoietic organ.

In another article Vaughan[39] has seen fit to lay some stress on a relationship of uric acid to nuclein. He cites those observations made in regard to an increase of uric-acid excretion after the exhibition of nuclein, and adopts the theory of its formation as a result of the leucocytosis and a disintegration of the leucocytes following.

There are, as Richter[40] points out, not only diseases accompanied by leucocytosis, without an increase of the uric-acid excretion, but also some where this substance is in excess, although no leucocytosis. In cirrhosis of the liver, which Vaughan has cited as an example of the association of uric-acid excess with leucocytosis, there is in reality not only no increase, but according to Klein and others, an abnormally low number of the colorless corpuscles. Vaughan has been equally unfortunate in his illustrations of drugs, supposed both to cause a leucocytosis and an increase of the uric acid. He names antifebrin and antipyrin as such drugs, whereas Horbacyewski[41] himself found these drugs contradictory in this regard, since according to him, although they increased the number of the leucocytes, the excretion of uric acid was diminished.

In conclusion, we shall briefly indicate what we think a fruitful field for future research, whether or not the true solution be found therein. There are good reasons for looking upon the eosinophilic leucocytes as very different and distinct from all the other white blood-corpuscles, not simply on account of their histological character, but also because of their different origin and different function. Neusser, for example, was led to think that they were produced by an irritation of the sympathetic system, and that eosinophilia was, so to speak, a secretory neurosis, in support of which theory he points to some interesting as well as confirmatory observations.

Kanthaack,[42] studying phagocytosis in the frog, after injections of anthrax, made some original observations as to the action of the eosinophiles. He noticed these cells were the first to come and apply themselves to the bacteria, though they did not take them up, the real phagocytes appearing only after an interval. He was accordingly led to believe that the eosinophiles had the function of preparing the particles for digestion, and he thought, although they were non-phagocytic, that

they performed the most important part in the struggle between the cell and microörganism. He suggested that perhaps the oxyphilic granules were of the nature of a zymogen and produced a substance of great chemical activity.

In accord with the idea that some important rôle is enacted by the eosinophile in the process of immunity, Hankin[43] has constructed his theory of the so-called "alexines," which are held to be a defensive substance to whose presence the serum owes its bactericidal property. It exists, according to Hankin, in normal life in the cells, but goes over in the lymph after death. He made certain experiments to discover if there existed a relation between the number of leucocytes and the bactericidal property of the serum, from which it was concluded that such a relation really existed, but that there was not a constant ratio. He believes that he has found by further experimentation, that the eosinophile cells were the source of the property in question, this depending upon the setting free of those cells into the fluid. The latter process, he demonstrated, took place but very slightly in a freshly produced leucocytosis, in which there was but a moderate bactericidal property; whereas it was much greater in an older leucocytosis, corresponding then to a higher degree of bactericidal activity of the serum.

The theory of the alexines or alexocytes was reviewed by Metschnikoff, and this author was disposed to make light of the rôle of the eosinophile in immunity, quoting various other authors who had attached but little importance to this cell in inflammation and infection. But it seems to us, the observation ought to carry little weight, seeing that he followed those authors who placed the normal limit of the eosinophiles at from five to ten per cent., whereas at the present day it is generally estimated to range between one and two per cent.

We had occasion in a former paper[44] to refer to the clinical fact that while measles, a disease in which the eosinophiles were scarce, was often followed by tuberculosis, marked likewise by a tendency toward a low number of those cells; scarlatina on the other hand, where eosinophilia was usually high, was notably seldom so followed.

This has suggested to us that we compare those diseases in which there occurs an augmentation of the eosinophilic leucocytes, with those which clinical experience has shown to be the least often associated with tuberculosis. The latter, that is diseases apparently antagonistic to tuberculosis, are acquired chlorosis, acquired heart lesion, primary essential asthma and emphysema, primary nephritis, uric-acid diathesis, carcinoma, and echinococcus. Leaving out the cardiac lesion and the carcinoma, everyone of these affections, strange to say, falls in the list of those marked by an increase of the eosinophiles.

This is the more remarkable because that list is not such a very comprehensive one. In addition to those indicated, eosinophilia is a feature only of leucemia, Basedow's disease, osteo-malacia, malaria, intestinal parasites and intoxication, two or three skin affections (pemphigos pellagra, and lymphoderma perniciosa), and certain functional neuroses, and pneumonia (at the crisis). May we not, if our suspicion be well founded, anticipate that further observations will show the same to be true of all affections in which there is great and constant increase of the leucocytes that contain oxyphilic granules? It is noteworthy in this connection to recall that several authors have seen that Koch's tuberculosin would give rise to an augmentation of the eosinophiles.

According to Poehl,[45] immunity is indebted to the existence in the blood and lymph, under favorable conditions, of a substance called "spermin." This is formed by a disintegration of the leucocytes, but only when this takes place in a sufficient alkalinity of the blood do we have a *soluble* spermin, in which form alone does it possess the power to afford immunity. The latter is due to a proper equilibrium in the process of tissue-change, the greater part of which consists in intraoxidation, and this condition depends upon this soluble spermin. Let it become converted into the insoluble form, which happens in a lowered alkalinity of the blood, then tissue-metabolism, and especially intraoxidation, is so interfered with that there is collected much incompletely oxidized material, accountable according to our author, for all kinds of auto-intoxication. Spermin phosphate is identical with Charcot-Leyden crystals, which were demonstrated by Goulasch to be the crystalline derivative of the eosinophilic cells.

So we again see this most recent of theories to explain immunity, though arrived at by other processes of reasoning and based on other physiological principles, amounts in the end to a quasi-substantiation of the views of Kanthaack, Hardy, and Hankin, as to the significant rôle played by the eosinophiles in protecting the organism against disease.

SUMMARY.

We may summarize briefly what has been brought out in the foregoing as follows:

1. Notwithstanding the long-continued conflict as to the importance of the cell and of the lymph

respectively, as the protecting agency of the body, it is probable the claims on each side will be found reconcilable.

2. There is no reason for regarding the leucocytosis, which appears after the introduction of nuclein into the system, as differently produced than that which follows from a great number of other agents, many of which are poisons.

3. Theories of artificially induced leucocytosis, which assume an essential new production of leucocytes by the blood-making organs, are inconsistent with the fact that the blood-making organs send forth only mononuclear cells, whereas in all these forms of leucocytosis the polynuclear are only or chiefly increased.

4. Also, Löwitt's theory of leucolysis and consequent leucocytosis fails to stand the test of experiment or of reason, in the light of known physiological principles.

5. The most rational explanation of leucocytosis is, including the invariable antecedent, leucopenia, according to the principle of chemotaxis. The predominance of polynuclear cells is thereby accounted for in the greater sensitiveness of these forms to chemotactic influences.

6. We must regard, therefore, a leucocytosis as only a local condition; that is to say, only a determination of the white cells into the peripheral circulation, without any real, significant, absolute increase of the whole number of those cells. This view is supported by a number of experiments, which showed that at the stage of leucocytosis as found in the peripheral vessels, there was a coincident decrease in the internal vessels.

7. The leucocytosis produced by nuclein is of this kind. The uric acid found in increased amount in the urine after administration of nuclein may be formed from the nuclein direct and not from the white blood-corpuscles. There is, moreover, no constant correspondence in the number of leucocytes and the amount of uric acid excreted, for there may be leucocytosis without increase of the uric acid, as there may be often an increase of uric acid without leucocytosis.

8. There is some reason for believing that, of all leucocytes, those possessed of the eosinophilic granules play the most essential rôle in protecting the organism against infectious diseases. A suggestive correspondence exists between those diseases which are distinguished by an augmentation of eosinophiles and diseases antagonistic to tuberculosis.

SURGERY BEFORE THE DAYS OF ANESTHESIA.[1]

By JOHN ASHHURST, Jr., M.D., LL.D.,
PHILADELPHIA.

Mr. President and Gentlemen of the Board of Trustees and Hospital Staff, Ladies and Gentlemen: A study of the condition of operative surgery before the days of anesthesia reveals on the one hand a picture of heroic boldness and masterly self-control on the part of the surgeon, and on the other a ghastly panorama, sometimes of stoic fortitude and endurance, sometimes of abject terror and humiliation—but always of agonizing wretchedness and pain—on the part of the unhappy victim, man or woman, whose necessities required a recourse to the surgeon's aid. And from our vantage-ground of a half-century's experience it is difficult for us to understand why it was not until fifty years ago to-day that the crucial experiment was made in this hospital, and that surgical anesthesia became a glorious reality.

It is somewhat difficult to obtain an accurate picture of pre-anesthetic surgery from the patient's point of view, probably for a similar reason to that indicated by the lion in the fable, when he criticized the artist for always representing a combat between lions and men as terminating in a human victory—lions do not paint. So, as operations are habitually reported by surgeons and not by patients, we read of the skill and intrepidity of the operator, of difficulties met and overcome, and of victories snatched as it were from the very jaws of impeding defeat; but we hear little of the tortures of the victim under the life-saving process, or, in an unsuccessful case, of the gradual subsidence of agonizing cries hushed in the silence of death. And yet we sometimes catch, incidentally, a side-glimpse of an operation from the patient's standpoint, and can thus form some faint notion of the shades as well as the high lights of capital surgery in days gone by.

Those who are familiar with the history of British surgery seventy years ago will recall the famous case of "Cooper *vs.* Wakley," in which the enterprising founder and proprietor of the *Lancet* was sued and mulcted, though in but nominal damages, for the report of an operation for lithotomy performed by Sir Astley Cooper's nephew, Mr. Bransby B. Cooper. The report opens with a quotation from John Bell, referring to "long and murderous operations, when the surgeon labors for an hour in extracting the stone, to the inevitable destruction of the patient," and then, having described in terms as graphic as uncomplimentary, the operator's prolonged efforts to remove the calculus, and the words which showed his own anxiety and discomposure during the process, adds: "Such were the hurried exclamations of the operator. Every now and then there was a cry of 'Hush!' which was succeeded by the stillness of death, broken only by the horrible squash, squash, of the forceps in the perineum. 'Oh! let it go—pray let it keep in!' was the constant cry of the poor man." The patient was on the table nearly an hour, and, after a night and a day of great pain, "death" adds the reporter, "ended the poor fellow's sufferings, about twenty-nine hours after the operation." The fatal result appeared to have been due to peritonitis. It is, indeed, not an unheard-of thing that a surgeon's presence of mind should fail him in a difficult operation even at the present day; but at least the patient, unconscious through the blessing of anesthesia, does not know it, and this complication is spared, to the great comfort of all concerned.

The "pitilessness" which Celsus urged as an essential trait in the operative surgeon—though Percy and Laurent declare that this pitilessness was meant to be apparent only—was, indeed, before the days of anesthesia, a feature in the surgeon's character which impressed very strongly the public generally as well as those immediately connected with the operation; and it may be feared that there are not wanting, even at this nineteenth century's end, some who would echo the comment of the younger Pliny upon the operative surgeons of his time: "They make experiments through deaths, and no head is secured from them."

It is interesting to recall that Sir James Simpson of Edinburgh, shortly after beginning his professional studies, was so affected by "seeing the terrible agony of a poor Highland woman under

[1] Delivered at the celebration of the Fiftieth Anniversary of the first administration of ether in a surgical operation, held in Massachusetts General Hospital, Boston, October 16, 1896.

amputation of the breast," that he resolved to abandon a medical career and seek other occupation; happily his intention was reconsidered, and he returned to his studies, asking himself, "Can anything be done to make operations less painful?" and, as every one knows, in less than twenty years became himself a high priest of anesthesia, and the introducer into surgical and obstetrical practice of ether's great rival, chloroform.

Not only did delicate women and tender children dread the ordeal of the surgeon's knife, but strong and brave men also recoiled from its use in horror: Buffon preferred death to relief from the agonies of calculus by the operation of lithotomy, and case after case is narrated by Monfalcon and other writers, in which men submitted themselves with the utmost calmness and fortitude to the hands of skillful operators, instantly falling into collapse after the first incision, and, without undue loss of blood, quickly succumbing to the depressing effects of simple shock and pain.

No braver or more gallant gentleman ever lived than Admiral Viscount Nelson, and after his right elbow had been shattered by a French bullet in the assault at Teneriffe, he manifested the utmost courage, refusing to be taken to the nearest ship lest the sight of his injury should alarm the wife of a fellow officer whose own fate was uncertain, and when his own ship was reached he climbed up its side without assistance, saying, "Tell the surgeon to make haste and get his instruments. I know I must lose my right arm, so the sooner it is off, the better." "He underwent the amputation," we learn from a private letter of one of his midshipmen, "with the same firmness and courage that have always marked his character." And yet so painfully was he affected by the coldness of the operator's knife, that when next going into action, at the famous battle of the Nile, he gave standing orders to his surgeons that hot water should always be kept in readiness during an engagement, so that if another operation should be required, he might at least have the poor comfort of being cut with *warm* instruments.

But the most striking picture of which I am cognizant, showing the way in which an intelligent patient looked upon a surgical operation, is to be found in a letter written to Sir James Simpson by a friend, himself a member of the medical profession, who had had the misfortune to lose a limb by amputation before the introduction of anesthesia: "I at once agreed," he says, "to submit to the operation, but asked a week to prepare for it, not with the slightest expectation that the disease would take a favorable turn in the interval, or that the anticipated horrors of the operation would become less appalling by reflection upon them, but simply because it was so probable that the operation would be followed by a fatal issue, that I wished to prepare for death and what lies beyond it, while my faculties were clear and my emotions were comparatively undisturbed. . . . The week, so slow, and yet so swift in its passage, at length came to an end, and the morning of the operation arrived. . . . The operation was a more tedious one than some which involve much greater mutilation. It necessitated cruel cutting through inflamed and morbidly sensitive parts, and could not be dispatched by a few strokes of the knife. . . . Of the agony it occasioned I shall say nothing. Suffering so great as I underwent cannot be expressed in words, and thus fortunately cannot be recalled. The particular pangs are now forgotten; but the blank whirlwind of emotion, the horror of great darkness, and the sense of desertion by God and man, bordering close upon despair, which swept through my mind and overwhelmed my heart, I can never forget, however gladly I would do so. Only the wish to save others some of my sufferings makes me deliberately recall and confess the anguish and humiliation of such personal experience; nor can I find language more sober or familiar than I have used, to express feelings which, happily for us all, are too rare as matters of general experience to have been shaped into household words. . . . During the operation, in spite of the pain it occasioned, my senses were preternaturally acute, as I have been told they generally are in patients under such circumstances. I watched all that the surgeon did with a fascinated intensity. I still recall with unwelcome vividness the spreading out of the instruments, the twisting of the tourniquet, the first incision, the fingering of the sawed bone, the sponge pressed on the flap, the tying of the blood-vessels, the stitching of the skin, and the bloody dismembered limb lying on the floor. Those are not pleasant remembrances. For a long time they haunted me, and even now they are easily resuscitated; and though they cannot bring back the suffering attending the events which gave them a place in my memory, they can occasion a suffering of their own, and be the cause of a disquiet which favors neither mental nor bodily health."

On the side of the surgeon, we find throughout the ages a constant effort to diminish the terrors of operations, and a continuous reprobation of

the distressful, not to say cruel, modes of practice adopted by preceding generations. "Who can read without a kind of horror," cries Monfalcon, "the account of those frightful operations which were then practised? And yet the time is not very far distant from ours, when they lopped off a limb by striking it violently with a heavy knife; that time when they knew neither how to stop nor how to prevent hemorrhage but by burning the part whence the blood jetted with boiling oil or the red-hot iron; that time when surgeons armed themselves at every moment with pincers, with burning cauteries, and with a thousand instruments, the representations even of which cause terror." Will it happen that on the occasion of some future anniversary, our successors will speak of our operative triumphs with the same scorn and abhorrence with which writers of the present day sometimes refer to the great deeds of our surgical forefathers?

The belief that operations might be rendered painless, and the hope that some means might be discovered by which this end should be accomplished, appear to have been present in the minds of surgeons from the earliest periods. Witness the accounts of the Memphis stone, described by Dioscorides and Pliny, which by steeping in vinegar was made to give forth the fumes of carbonic acid; and of the Mandragora, employed according to Theodoric, when mixed with other narcotics, by inhalation, and causing a sleep from which the patient could only be aroused by the fumes of vinegar; so profound was the stupor induced by this drug, that Bodin assures us that under its influence a man submitted without consciousness to a painful operation, and continued to sleep for several days thereafter.

Vigo speaks of the whole body being "brought asleep by the smelling of a sponge wherein opium is," but warns his readers that the practice is dangerous, because the use of opium is sometimes followed by gangrene. In his work on "Natural Magic," Baptista Porta speaks of a volatile drug, kept in leaden vessels, which produced sleep when applied to the nostrils, and Perrin suggests that this may actually have been ether or some other of our modern anesthetic agents.

Others endeavored to prevent the pain of operations by mechanical means. The Assyrians, Hoffman assures us, compressed the veins of the neck, apparently by tying a band around the part, before practising circumcision, and compression of the carotid arteries was suggested as an anesthetic measure in more modern times by Dr. Fleming; while still more recently, Dr. Augustus Waller has shown that insensibility may be induced by compressing the cervical vagi. Garroters have indeed clearly shown, as remarked by Simpson, that a person may readily be choked into unconsciousness, but it is not surprising that their mode of practice has not commended itself to surgeons for general adoption.

Compression of the limb by a fillet or tight ligature, before amputation, is referred to by Paré as a mode of alleviating the suffering which attends that procedure, and Benjamin Bell tells us that "in amputating limbs, patients frequently desire the tourniquet to be firmly screwed, from finding that it tends to diminish the pain of the operation." The same writer refers approvingly to the suggestion of Mr. James Moore, that pain should be controlled by the application of a screw compressor to the principal nerve of the part, but surgeons generally appear to have agreed with Monfalcon, that the inconveniences of such an apparatus fully equaled its very slight advantages.

Mental preoccupation was sometimes sought as a means of preventing pain. Richard Wiseman found that soldiers dreaded the loss of a limb much less if it was removed immediately, while they were "in the heat of the fight," than if the operation was postponed until the next day; "wherefore," he says, "cut it off quickly, while the soldier is heated and in mettle;" and Renauldin recalls the case of the amiable Dolomieu, who, exposed to the pangs of starvation in a Neapolitan dungeon, measurably alleviated his own distress by engaging in the composition of a treatise on mineralogy, while his unfortunate servant and fellow prisoner, who had not the same intellectual resources, was hungry enough for both.

But the presence of pain was not the only evil dreaded by our predecessors in attempting important operations; the great risk of fatal accident from some involuntary movement of the patient was constantly present to the mind of the conscientious surgeon. "How often," says Dr. Valentine Mott, "when operating in some deep, dark wound, along the course of some great vein, with thin walls, alternately distended and flaccid with the vital current—how often have I dreaded that some unfortunate struggle of the patient would deviate the knife a little from its proper course, and that I, who fain would be the deliverer, should involuntarily become the executioner, seeing my patient perish in my hands by the most appalling form of death! Had he been insensible, I should have felt no alarm." So

greatly was the responsibility of using the knife felt by the best-informed surgeons of pre-anesthetic days that many, like Haller, distrusted their own manual dexterity, and declined to perform operations which, while recognizing as necessary, they felt should be left to other surgeons differently constituted from themselves. Would that a little of this Hallerian diffidence might affect some tyros of the profession in our own day who, without the slightest preliminary practical training, do not hesitate to undertake the most hazardous procedures, and seem to consider themselves disgraced if they cannot count one or more abdominal sections, even if terminating fatally, within the accomplishments of their first year's practice!

Coming down to the days more immediately preceding the date of the great discovery, we find that opium and alcohol were the only agents which continued to be regarded as of practical value in diminishing the pain of operations, though the attendant disadvantages of their employment were, of course, recognized. "Previous to every painful operation," says Dorsey, "a dose of laudanum should be administered." "I was in the habit," says Dr. Mott, "of giving opiates freely before the introduction of anesthetics, both before and after operations, . . . and opium and its preparations are the only anodynes well adapted to surgical use. No substitutes are worthy of confidence." Demme tells of a woman who, under the influence of opium, submitted to amputation at the hip-joint, and emitted but a single cry; and I myself recall distinctly patients who, in the hands of that excellent surgeon, the late Dr. George W. Norris, had limbs amputated with almost no manifestation of pain when saturated previously with opium and whisky. Alcohol, pushed to the point of producing intoxication, was employed as an anesthetic by some surgeons, and Dorsey tells us that Dr. Physick, following Richerand's suggestion, used it successfully for its relaxing effect in a rebellious case of dislocated jaw, in which, on account of the patient's "extreme debility," it was not thought prudent to resort to the usual remedy—"bloodletting *ad deliquium animi*."

Meanwhile facts were accumulating, the significance of which we can now plainly recognize, but which excited no attention at the time. Sir Humphrey Davy had, in the very early days of the nineteenth century, experimented with nitrous oxid gas, afterward employed by Horace Wells, and had, in so many words, suggested its use as an anesthetic in minor operations; its power of preventing the sensation of pain was well known to many persons, and it was the custom at some of our medical schools, noticeably at the University of Pennsylvania, for students to breathe the "laughing-gas," as it was then called, for diversion. The use of ether by inhalation had been still earlier recommended by Beddoes, Pearson, and Thornton as a remedy for certain diseases of the lungs, and in 1805 your own Warren had employed it "to relieve the distress attending the last stage of pulmonary inflammation." Its intoxicating qualities when inhaled, and its power, when in sufficient concentration to produce stupefaction, had been recognized in 1839, in Pereira's well-known treatise on materia medica, and were quite familiar to American medical students; and it is no doubt possible—I certainly have no wish to deny it—that in isolated cases it may have been used as a means of relieving pain by individual practitioners, as by Dr. Long, of Athens, Ga., whom Perrin, with that happy disregard of the geography of all countries except their own, which is characteristic of French writers, calls the "Greek physician."

But yet—and yet—surgeons went on, in every country, cutting and burning, and patients went on writhing and screaming, until, on the sixteenth day of October, in the year 1846, in the Massachusetts General Hospital, Dr. John C. Warren painlessly removed a tumor from a man who had previously been etherized by Dr. William T. G. Morton, and surgical anesthesia became the priceless heritage of the civilized world.

CLINICAL MEMORANDA.

SUCCESSFUL LAPAROTOMY AND KRASKE OPERATION ON AN INFANT TWO DAYS OLD FOR IMPERFORATE RECTUM.[1]

By J. W. ELLIOT, M.D.,
OF BOSTON;
SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL.

On May 1, 1896, an infant two days old was brought to me at the Massachusetts General Hospital, with the history that it had passed no meconium since birth. The child weighed six pounds ten ounces at birth. Examination revealed a perfectly formed anus, which proved to be a blind pouch less than a quarter of an inch deep. The abdomen was distended and hard. The little finger was easily passed into the vagina, but detected no bulging of the bowel.

An incision was made from the anus to above the level of the top of the sacrum. After a few minutes' dissection, it became evident that the lower rectum was entirely absent. The posterior wall of the vagina bulged into the

[1] Reported at the American Surgical Association at Detroit, May 28, 1896.

wound, and was opened in order to inspect its upper end. The coccyx was next removed with scissors, but no portion of the rectum could be found. The lower part of the sacrum was next cut out on the left side, up to about the third foramen, making a regular Kraske operation. The finger was then pushed in just in front of the sacrum to a considerable depth, but the bowel could not be felt. The child was then turned on its back in the Trendelenburg position, and the abdomen opened in the median line. The urachus and the bladder were met lying against the abdominal wall and were avoided.

The lower bowel was found to consist of a greatly distended pouch which filled the abdomen and seemed to spread out over the whole pelvis, but not to enter it. Its distended condition prevented my pushing it down into the pelvis. A trocar was passed in through the sacral wound, and with two fingers in the abdomen to guide, it was pushed into the distended bowel. Gas escaped freely, and as soon as the bowel had collapsed, I was able to push it down in front of the sacrum until it was caught in the sacral wound, where it was opened and stitched to the skin as in a regular Kraske operation. The abdominal and perineal wounds were quickly closed with sutures.

The infant bore the operation remarkably well. Great care was taken to keep it warm. It was fed on modified milk, according to Dr. Rotche's formula.

The temperature rose to 102° F., and pulse, 140. On the fifth day the temperature was normal, and gas and feces passed freely through the artificial anus. The child gained nearly two pounds in the next three weeks, and was discharged from the hospital on the twenty-seventh day in good condition. The wounds had healed rapidly, and the opening into the rectum was large and needed no dilatation.

A letter from the parent, a doctor, three months after the operation, reported the child in excellent health, but the opening into the rectum had required dilatation.

So far as I am able to learn from the literature, the coccyx has been removed several times in searching for the bowel in cases of so-called imperforate rectum. Dr. Conant[1] appears to have been the first to do a laparotomy for the purpose of pushing the bowel down into the perineal wound.

The case here reported, I believe to be the first where a laparotomy was combined with a Kraske operation for the correction of imperforate rectum.

REPORT OF A CASE OF TYPHOID FEVER COMPLICATED BY EXTRAUTERINE PREGNANCY.

By JAMES B. HERRICK, M.D.,
of Chicago, Ill.

I DESIRE to place on record the following case, because of the rare, if not unique, combination of typhoid fever and extrauterine pregnancy.

A woman, about thirty-eight years of age, entered the Cook County Hospital, January 25, 1896, with many of the initial symptoms of typhoid fever—headaches, chilliness, anorexia, malaise, fever for several days, etc. No splenic tumor or rose-spots could, however, be made out at this time, and a diagnosis of typhoid was, therefore, reserved. This reservation was also made, because of the suspicion of a puerperal or *post-partum* septicemia. The patient told us that a few weeks before, being, as she then supposed, three months pregnant, she had taken medicine to bring on an abortion and had, as she believed, accomplished the object. For there had been a discharge of blood with some other material, that she described very indefinitely, but which she thought was the fetus. This continued for nearly three weeks, and then she suffered from the loss of appetite, the headache, the chilliness, etc., that finally induced her to come to the hospital. A fact that she reported, and which, in the light of later revelations was very significant, but to which not enough importance was attached in the making of the diagnosis, was that about this time, *i.e.*, the time of the supposed miscarriage, she had suffered severe abdominal pain, nausea, and had an attack of fainting, with some form of convulsion.

The examination gave the ordinary findings in a fever patient. In addition, there was plainly made out what was believed to be an enlarged uterus, presumably four months advanced in pregnancy. The question of its containing a live or dead fetus, secundines, or a fibroid, was discussed as well as the possibility of its being the source of infection. The absence of odor, discharge, or evidence of local uterine or peritoneal inflammation, with the many indications of typhoid, led to an expectant and non-interfering policy. This was rewarded in a few days by the appearance of rose-spots, and by such enlargement of the spleen as to make this organ plainly palpable. The diagnosis was further confirmed by an intestinal hemorrhage that proved fatal. The urine had shown on all examinations an abundance of albumin with numerous casts.

The autopsy (Drs. Hektoen and Tice) revealed healed apical tuberculosis, old pleuritis, pericarditis, endarteritis, chronic nephritis, and a ureteral anomaly. The findings, to which I call attention, were:

1. *Typhoid fever.*—Typical typhoid ulcers in ileum and colon; enlarged mesenteric glands; splenic tumor; typhoid bacilli in spleen, kidney, and heart's blood.

2. *Extrauterine pregnancy.*—The uterus was slightly increased in size and pushed to the left. Back of the uterus, occupying the middle of the pelvis and rising above its brim, was a globular mass containing a mummified fetus, placental tissue, and an old blood-clot. This mass was bound to the surrounding intestines by firm adhesions. The right tube could be traced for but half the length of the left. Apparently there had been primary right tubal pregnancy, with rupture at the time of the pain and syncope.

I have been unable to find other records of this unusual accidental complication of typhoid fever, and report the case, therefore, because of its rarity. It also teaches the lesson that it is not always wise to resort to operations—even exploratory operations—until the diagnosis is reasonably clear. It is often good practice to wait for hours or days before deciding as to the nature of an illness or the

[1] *Boston Medical and Surgical Journal*, March 24, 1892.

method of treatment proper to be employed. Had operative interference been resorted to, in this case, for the removal of a possible uterine source of infection, death would probably have resulted earlier than it did, and from the effects of the operation. The patient with typhoid and chronic nephritis would have been a poor subject for the surgeon. Had we been more skillful in recognizing the extrauterine pregnancy, the temptation would have been very strong to have looked upon the case as one of infected gestational sac, and clearly suitable for immediate operation. Fortunately, we temporized, and the death cannot be attributed to too zealous or unskilled treatment, but solely to acute anemia following intestinal hemorrhage.

MEDICAL PROGRESS.

A New Method of Diagnosis in Typhoid Fever.—In *La Presse Medicale* (July 29, 1896) WIDAN describes a method used by him as a test for the diagnosis of typhoid fever, which has not failed in eighty cases examined. The test rests upon the action of the serum of a typhoid patient upon young cultures of coli bacilli growing in bouillon. It is performed in several ways. From a finger-tip carefully sterilized by bichlorid of mercury solution and ether a small quantity of blood is drawn into a glass receptacle and allowed to clot. If a few drops of the serum (one for every ten drops of bouillon) are introduced into a young bouillon culture of coli bacilli, these will in a short time gather themselves together into little balls, sometimes visible to the naked eye and always easily noticeable by the aid of the microscope. The reaction may be evident in a few minutes, but is more marked after a few hours. It is desirable to use a culture of the bacilli only a day or so old; but if no fresh one is at hand, another method may be used. A tube of bouillon is sowed with some of the old coli bacilli culture (no fresh culture being at hand), and the typhoid serum is added in the proportion of one drop of serum to three cubic centimeters of bouillon. After twenty-four or forty-eight hours at 37° C. the same reaction described above is discernible. A control tube is recommended, the coli bacilli being omitted as the blood-serum may not be sterile.

Effect of Ether on the Blood.—The author of this paper, VON LERBER (Inaug. Diss., Basel, Schweiz. Verlagsdruck, 1896) bases his conclusions on examinations of the blood of 101 patients. One or two examinations were made before etherization, and from two to four examinations afterward.

The quantity of hemoglobin was compared in ninety-eight cases. In sixty-five cases it was the same after operation as before; nineteen times there was an increase, fourteen times a diminution, but in only two instances did this amount to ten per cent., and in these there was great loss of blood at the operation. Ether, therefore, does not affect the quantity of hemoglobin.

The red blood-cells were counted in 101 cases. In fifty-five cases they were increased, in forty-two diminished, and in four there was no change. The gain and loss were in most cases only temporary. So that it may safely be said that ether has no deleterious influence on the red blood-corpuscles. A spectroscopic examination of the urine in eighty-three cases failed to show any increase in urobilin. This is further evidence that the red blood-corpuscles were not destroyed.

In ninety-six cases the white blood-corpuscles were increased. In five they were diminished. In three of these latter the opening of abscesses (which had caused pathological leucocytosis before the operation) sufficiently explained the decrease in white corpuscles. In one case the decrease seemed due to rapidly approaching death, and in the other case the decrease was insignificant. The author concludes that etherization often occasions a marked leucocytosis.

Division of the Cervical Sympathetic in Cases of Exophthalmic Goiter.—JABOULAY (*Lyon Médical*, 1896, No. 22, p. 150) has practised division of the cervical sympathetic nerve in two cases of exophthalmic goiter, with resulting diminution in the prominence of the eyes. Both nerves must be divided, but the result is not always symmetric, as one of the nerves may be larger than the other, and thus capable of more pronounced activity. The operation is believed to be justifiable in accordance with the intensity of the symptom.

Cæsarean Section Thrice Performed on the Same Patient.—VAN DE POLL (*Centralblatt für Gynäkologie*, 1896, No. 21, p. 554) has reported the case of a woman whose first pregnancy terminated in the spontaneous delivery of a putrid fetus; the second in the instrumental delivery also of a putrid fetus. In the third labor, after the discharge of a considerable amount of amniotic fluid, the fetus was found to occupy a transverse position, an arm prolapsing. Decapitation was performed and the body of the child extracted. During the necessary manipulations it was found that the pelvic inlet was greatly contracted, but the head was expressed with some little effort. The head and the placenta were in process of putrefaction. Rigid antisepsis was observed, and the puerperium was uncomplicated. Subsequent measurement showed the pelvis to be of generally contracted, flat, rachitic type. The patient was instructed in the case of another pregnancy to present herself for Cæsarean section; and accordingly, about a year later, this operation was performed, the child living, and the only complication being a mild circumscribed peritonitis. Some 2½ years later the woman again became pregnant, and again was Cæsarean section performed, with the delivery of a living child. After an interval of seven years the woman became pregnant for the sixth time. After incision of abdominal wall and uterus a slightly asphyxiated child was delivered and resuscitated. On account of the firm adhesions between the anterior surface of the uterus and the abdominal wall it was decided to remove the uterus by the method of Porro, and a portion of the abdominal wall, which was the site of adhesions, was excised. Continuing hemorrhage from the vagina, after closure of the abdominal wound, necessitated reopening, and a small bleeding vessel was ligated. Other than a slight diarrhea the further progress of the case was uneventful.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SALINE INJECTIONS.

In a recent number of the *Revue de Chirurgie*, Claisse gives a study of the effects of the subcutaneous injection of saline solutions in man and the lower animals. In view of the rapidly increasing practice of combating certain diseased conditions by the injection of serums, real or artificial, a resumé of the subject is well worth a few moments' thought. The solutions most often employed are such as the following:

Sodium chlorid	7 grams
Distilled water	1000 grams

Or

Sulphate of soda, Chlorid of soda aa	7 grams
Distilled water	1000 grams

The solutions are injected at the body temperature. It has been found by experiments upon animals that there is what is known as a toxic rapidity of injection, and if this be exceeded the animal quickly dies; but it has little practical application in man, as this limit could be reached only by the greatest recklessness.

As might be expected, the most satisfactory results have been obtained in cases of exsanguination, and clinical and experimental results agree that the injected serum not only supplies in quantity the place of the blood lost, provided the hemorrhage has not been too great, but that it has a decided hemostatic action. The clinical phenomena which follow these large injections in cases of acute anemia or of shock, have deeply impressed those who have witnessed them. Patients who were blanched, cold, senseless, and almost without pulse and respiration, have shown a marked improvement before 100 grams of fluid were injected. With the continuance of the treatment, pulse and respiration became normal, the cheeks regained their color, and the eyes their brilliancy, and consciousness returned. With the injection of 1½ to 2 liters, reanimation was complete, though in several instances it was necessary to repeat the treatment once or twice.

The results of saline injections in infection are none the less interesting, although they are less clearly understood, and the treatment in such conditions has been far less satisfactory than in acute anemia. The clinical observations here have mostly rested on the results in pneumonia and cholera, and such surgical affections as septicemia after child-birth or surgical operations. In a recent article in *La Presse Médicale*, June 17, 1896, Bosc has gone into this part of the subject very thoroughly, and a typical case must here suffice.

Take a patient suffering from a severe infection—puerperal, for instance; all the organs are affected and are working badly, the temperature is about 104°; in ten minutes 1300 or 1400 grams of saline solution are injected subcutaneously. Before half of that amount has been reached, the improvement is manifest. The pulse becomes more regular, fuller and stronger; respiration is deeper and less hurried, and possibly the temperature falls a degree at the end of the injection. The patient feels better, is brighter, and possibly desires to urinate, but not any great amount.

Usually the patient now enters what is known as the *critical stage*, which comes on generally in four or five minutes, though it may be delayed to half an hour. There is a violent chill, with sensation of extreme cold, strong, rapid pulse,

and a rapidly rising temperature (104°–106° in the space of an hour). The chill is succeeded in from forty to sixty minutes by a feeling of heat, with flushed face, injected conjunctivæ, and labored respiration. Pulse and temperature are unchanged. Water makes its appearance in quantities through the pores of the skin, the kidneys, and sometimes the intestinal tract.

Three or perhaps four hours later the real improvement becomes manifest, the temperature sinks to normal—often very rapidly—and convalescence is entered upon. In severe cases the improvement is only temporary, and the injections have to be repeated in thirty-six or forty-eight hours. In still other cases the injections have little effect in staying the fatal issue.

Such, in general, are the results of subcutaneous saline injections, corresponding to intravenous ones, except that the latter produce a more marked *critical stage* and a somewhat quicker improvement. What can be said of their mode of action?

1. The mode of action in acute anemia is relatively simple. The gravity of this condition is due to the rapid fall of arterial pressure, the cardiac reflex is imperfectly excited, and the heart contracts irregularly and feebly. As soon as the vessels are filled the heart beats again with its usual force, and the anemia of the nervous centers disappears. The injections produce hemostasis in a twofold way, by exciting the contractors of the torn arterioles, and by the precipitation of hematoblasts, thereby favoring clotting of the blood.

2. In infectious cases the mode of action is still very obscure. It is not a simple mechanical one, by which bacteria and toxins are washed out through the skin, kidneys, and intestine—a "lavage of the blood," as it has been called. The quantity of fluid used is too small for that, and an actual toxiuria has not been proven. No, the action is more complicated.

In infection, all the general symptoms point to an intoxication whose effects are especially evident upon the nervous system. The rapid effect of injections can only be explained by a destruction of the toxins or an almost instantaneous increase in the resisting power of the body. But the transformation of toxins by the injection of 1200 grams of salt water is problematical, to say the least. Still it has been thought possible, by Chorrin. On the other hand, that the physiological resistance manifests a renewed and intense activity seems more likely.

Phagocytosis undoubtedly plays an important part in the protection of the tissues. It may be that the gravity of infection is due in part to an insufficient activity of the leucocytes. This in turn may be due to hypertoxicity of the blood. Perhaps the salt water reduces this toxicity by simple dilution of the blood, and conveyance to all parts the nourishment necessary for cellular activity, thus renewing the strife between the forces of infection and resistance.

This theory is based on too scanty facts, it is true, but as far as known the results of saline injections are comparable to those of the injection of antitoxic serums—*i. e.*, they produce disintoxication.

If this theory is admitted the explanation of the symptoms which follow is easy. Freed from the influence of the poison the nervous system resumes its action. The increased quantity of fluid and the better nervous action give a stronger and more regular pulse, and the kidneys and skin in consequence resume their functions, and the temperature gradually returns to normal.

The indications for the use of saline injections after profound hemorrhages are absolute, and intravenous injections are preferable to subcutaneous ones on account of their more rapid action. In serious infections (acute peritonitis, puerperal or traumatic septicemia, tetanus, eclampsia), where a temperature of 103°, or higher, shows a grave pathological condition, this method of treatment not only ought to be, but should be wisely and judiciously applied in connection with sustaining treatment.

Claisse concludes that "These large injections of saline solution ought to be employed with judgment and prudence, as a very powerful therapeutic resource." In them we possess an agent which, logical in theory, approved by experiment and clinical experience, is able to give happy results in conditions which have hitherto seemed beyond the resources of medicine.

THE JUBILEE OF ANESTHESIA.

The condition of anesthesia is such a common one that the present generations of surgeons little realize what a priceless boon to humanity its discovery was. It is well, therefore, in the celebration of the fiftieth anniversary of that event, to recall the pre-anesthesia days; and in that respect the celebration in Boston was made peculiarly interesting by the presence there of some of the prominent actors in the surgical arena of that time who were present when the first demonstration was made of the complete anesthetic powers of sulphuric ether. In this demonstration Morton was the prominent figure, and it was largely due to the power of his unalterable conviction that ether could be harmlessly taken to the extent of causing complete unconsciousness during a surgical operation that this great triumph was made possible. It is the act of Morton, therefore, that is rendered memorable by this anniversary celebration.

He it was who, in the Massachusetts General Hospital, on the 16th day of October, 1846, in the face of skepticism and an assemblage of distinguished but doubting observers, dared to administer sulphuric ether to a fellow man, to the extent of rendering him insensible to the incisions made by the surgeon's knife.

There are four claimants to the honor of the discovery of anesthesia—Dr. Long of Georgia, Dr. Wells of Hartford, Conn., and Drs. Morton and Jackson of Boston. The late Dr. Marion Sims proved beyond question that Dr. Long performed one or two minor operations with the assistance of ether, in 1842, but Long did not publish the fact nor did he make known the process to the profession in a way to cause its adoption. Dr. Wells discovered the anesthetic effect of nitrous oxid gas. To demonstrate its efficacy he submitted to the extraction of one of his own teeth while under its influence, and afterward used it for that purpose in his practice of dentistry. Dr. Jackson suggested to Morton that if nitrous oxid gas would obviate pain, sulphuric ether would do it also, but Morton proved it.

It is not to be wondered at, that the honor of a discovery fraught with such inestimable importance to the human race, and indeed to the entire animal kingdom, should be sought by everyone who had the least claim to the distinction. Every great discovery is gradually led up to by a series of experiments or preliminary discoveries. An abstract truth is of importance because of its possibilities of practical beneficial application, and to the discoverer belongs due credit, but the man who conceives of and demonstrates the practical application, and so confers the blessing on humanity, deserves the greater honor. This seems to have been the fortunate rôle that Morton played in this great discovery.

Boston has the proud distinction of being the scene of this momentous act, and the nations of the earth recognize that to America belongs the honor of giving anesthesia to the world.

THE NEW YORK LUNACY LAW.

The lunacy law which passed the New York Legislature last winter, and which has recently been put into execution, does not seem to be the "gladsome light of jurisprudence" that was expected. Its workings, and especially its shortcomings, were made the special subject of discussion by the New York Neurological Society at its meeting, October 6th; a general expression was asked for and it was given. The consensus of opinion seemed to be that the law had not only failed to accomplish what its instigators and framers promised, but that serious difficulties, in the temporary disposition of violent patients had been interposed by the long and tedious formalities of the new plan of commitment. The lack of any provision for the care of patients, subject under the previous law to the five-day commitment on the certificates of two physicians, without judicial attestation, also presents a most serious objection.

With this exception it was clear that the physician who acts as examiner in lunacy has very little grievance against the new requirements. It is true, the additional formality which the law now imposes may consume more of his time for its satisfaction than did the previous method of commitment, but he will probably require no instruction to make an additional charge to the patient for this increased service. As a matter of fact, it is the patient and the patient's

family on whom the strictures of the law, some of which we believe unnecessary, weigh too heavily. The physician is concerned only in so far as he is responsible to himself and the friends for the patient's welfare, until such time as the commitment papers can be obtained. Under the existing conditions he has only to examine the patient and certify that in his opinion the patient is insane, and if we mistake not the papers can then be handed to an attorney, who will attend to all the rest of the formality without the physician's presence, even without the latter's appearance before the judge who makes the commitment.

It was made clear by one of the speakers that in the case of the pauper insane of this city it was impossible to satisfy the requirements of the law in reference to the petitioner, for many of these patients are without family or friend to pray the court that such an examination be made, and that in reality this stipulation must either be evaded, or the work must fall upon the city examiners, of whose duty it is not a part.

There exists, therefore, the greatest urgency for the amendment of this law, to the effect that the insane may be cared for until the necessary amount of red tape is unrolled to carry them to a permanent haven. We sincerely hope that the committee, which the Neurological Society has made provision for under the adopted resolution, will leave no stone unturned in the praiseworthy efforts to secure such an amendment to the law, which shall be directly contributory to the welfare of the patient, of his neighbors, and property, during the interim between the time of certification and the commitment. Our advice is that all their energies be directed to that effort alone, and that the matter of the petitioner, of the taking of additional testimony, of appeal, etc., which the new law provides for, be disregarded. If these are defects, their consequences are not serious, and they will succumb through the process of evolution to the exigencies of circumstances.

ECHOES AND NEWS.

Dr. Peabody Better.—Dr. George L. Peabody of New York, who was stricken with a severe attack of appendicitis at Gaspé, Canada, and operated on by Dr. Shepherd of Montreal, is now convalescent.

The Brooklyn Naval Hospital.—Secretary Herbert has adopted the plan submitted in competition by Smithmeyer, the designer of the Congressional Library, for the new ward of the Brooklyn Naval Hospital.

Queen Victoria's Eyesight.—An oculist named Pagenstecker says that Queen Victoria is suffering only from the natural effect of advancing years, and has made her some new glasses with which she can read and write about as well as ever.

The Bubonic Plague at Bombay.—From October 2d to October 7th there were ninety-seven fresh cases of bubonic plague at Bombay, and there have been 276 deaths. A quarantine against Bombay has been declared at Aden and Egyptian ports.

Against Restriction of Animal Experimentation.—The American Association of Obstetricians and Gynecologists at their session in Richmond adopted a resolution protesting against the proposed legislation by Congress restricting animal experimentation in the District of Columbia.

A Newly Discovered Constituent of the Blood.—Dr. Müller of Vienna has described certain particles found in the blood under the name of hæmokonia (blood-dust). They resemble fat-globules, and the largest are $\frac{1}{25000}$ of an inch in diameter. They are motile and are unaffected by osmic acid.

No Foreign Titles for Dentists.—A dentist has been arrested and fined in Berlin for displaying upon the door of his office a plate describing him as a doctor of dentistry from an American college. The court held that it was against the law for him to use a foreign title in practice in Germany.

Hospital Sued for Alleged Negligence.—Suit has been brought against the New York Post-Graduate Medical School and Hospital to recover $25,000 damages because of the death of a woman, which her father's attorneys allege was due to gross negligence and improper treatment by the hospital surgeons and attendants.

Southern Surgical and Gynecological Association.—The ninth annual meeting of the Association will be held in Nashville, Tenn., Tuesday, Wednesday, and Thursday, November 10, 11, 12, 1896. The Nicholson House has been selected as headquarters of the Association. The program promises an interesting and instructive meeting.

Pruritus Vulvæ in the United States.—*The Medical Press* says that everyday gynecological practice in Great Britain does not reveal pruritus vulvæ as a common or intractable affection, so that an explanation of its greater incidence on the other side of the Atlantic must be sought in ethnological or climatological peculiarities, unless there are more individual reasons associated with the prevalence of a highly strung, quasi-neurotic temperament.

The New York Milk Supply.—The inspection of the milch-cows which are kept within the city limits of New

York discloses a large percentage of tuberculous animals. The tuberculin test has been applied to 308 cows, and 52 of these, or nearly 17 per cent., have been found to be diseased. In one herd of 34 cows, the milk from which was sold to about 200 families, 11 were shown to be "consumptives;" in another herd of 12 there were 8 "consumptives," and the milk had been sold to 125 customers in the northern part of the city.

Health of the U. S. Army.—Surgeon-General Sternberg in his report for the year ended June 30, 1896, says: "All the rates that are usually considered by statisticians as throwing light on the physical condition of a community have been lower than in any previous year of the recorded history of the army. The number constantly sick was 35.89 per thousand of strength, as compared with 31.19 during 1894, and 41.59 as the average annual rate of the preceding ten years. The mortality rate from all causes was 5.16 per thousand of strength, as compared with 6.69 in 1894, 7.85 for the preceding decade, and 6.33 in 1889, the year of lowest record."

Drunkenness and Unprofessional Conduct.—The Medical Board of Oregon was recently called upon to decide what constitutes unprofessional and dishonorable conduct on the part of a physician, it being a duty of the board in its legal province to revoke the license of any practising physician guilty of "moral turpitude." It was established that a physician may get drunk and indulge in loud language occasionally without his conduct being held to indicate moral turpitude. On this point the board agreed with ex-United States Senator Dolph, who appeared as counsel for the accused physician, and who held that getting drunk was only a violation of a city ordinance, and, even when frequently repeated, did not involve any inherent baseness of character.

A Double Water Supply for London.—The *Lancet*, of August 29th, refers to a recent law called the "London Sea-water Supply Act," and urges that the construction of necessary works be begun at once. The enterprise is in the hands of a private corporation, whose primary object appears to be the introduction of sea-water for bathing purposes. The *Lancet* holds that its application will not be allowed to stop there, and that the water will be used in watering the streets, a duty that is very much in arrears, and especially noticeable by American tourists—and for other sanitary purposes. The *Lancet* regrets that the proposed intake of water is only a short distance removed from the outlet of the Worthing sewerage system, and maintains that care should be taken to get a sea-water supply that shall be free from contamination by sewage. As to the use of sea-water for household sanitary purposes, all that the *Lancet* has to say is, that it seems absurd to use one and the same water supply for drinking and flushing, and points out the enormous saving in potable water—at all times now so lamentably scanty in London—if sea-water can be utilized for sanitary purposes.

Chicago's Water Supply.—Mayor Swift of Chicago has been authorized to select three eminent engineers who will report a plan for constructing intercepting sewers, whereby the sewage, now poured into the lake where it contaminates the water supply, will be diverted to the drainage canal. The percentage of increase of typhoid thus far in 1896 is 71 in excess of that in the corresponding period of 1895. This is very nearly the death-rate per 10,000 of population of the year 1889, immediately preceding the typhoid fever epidemic of 1890-'92. The present proportion of deaths from typhoid fever is 3.17 per cent. of the total from all causes. In 1889 it was only 2.67 per cent. Health Officer Reilly pointed out to the Council that the legal value of human lives sacrificed to typhoid fever in Chicago during the past twelve months amounts to $3,750,000. The actual money cost of medical treatment, etc., of the cases will easily raise the sum to $5,000,000. In Duluth suit has been brought against the city water company by a wife for the death of her husband. She alleges that impure water caused his death. If she recovers damages, Dr. Reilly asked, what precedent might not her success furnish for suits against the city of Chicago?

Chelidonium Majus in Cancer.—Dr. Denisko of the Hospital at Briansk, has, it is alleged, obtained some remarkable results in the treatment of carcinomatous tumors by means of a preparation of great celandine (*Chelidonium majus*). He prescribes from twenty-three to seventy-five grains of the extract, to be taken daily in water or peppermint water, and, in addition, injects into the substance of the tumor, near its circumference, a mixture consisting of equal parts of the extract, water, and glycerin. At each sitting fifteen drops are injected altogether in several insertions. Moreover, the surface of the tumor, when ulceration has commenced, is painted twice daily with a mixture of one or two parts of the extract and one of glycerin. The patients usually bear the internal administration of the drug well, and the outward applications cause but very little smarting. The injections, however, in addition to local smarting, cause a sensation of languor, rigors, and some pyrexia, these phenomena commencing about a quarter or half an hour after the injection. They disappear entirely before the next day. Caution is, however, necessary, and the doses have to be suited to the idiosyncrasies of the patient. In a very few days the sallow discoloration, constantly seen in the skin of cancer patients, disappears and the tumor becomes softer. After four or five days small fistulæ begin to show themselves where the needle has been inserted, and around these the tumor gradually breaks down. In from fifteen to twenty-five days there is a complete zone or line of demarkation between the healthy and the cancerous tissue, the tumor decreases to half its former size, and any neighboring glands that may have been affected return to their normal condition. It should be clearly understood that the results alleged above are those claimed by Dr. Denisko to ensue on the treatment. We wish this to be made absolutely clear because, in the case of a disease which has hitherto proved to be so intractable to treatment by drugs as has cancer, we think it is wicked to raise false hopes in the breasts of sufferers and their friends.—*London Lancet*, August 29, 1896.

CORRESPONDENCE.

A PROTEST.

To the Editor of THE MEDICAL NEWS:

SIR: My name has been recently coupled with a recommendation of a certain patented disinfectant. This has been done in the newspapers and also in some of the medical magazines. I wish hereby to protest emphatically against any such use of my name. It has been done without my knowledge or consent.

Respectfully,

B. MEADE BOLTON.

BACTERIOLOGICAL DIVISION OF THE BOARD OF HEALTH.
Philadelphia, Pa., October 6, 1896.

SPECIAL ARTICLE.

TYPHOID FEVER AT LEAGUE ISLAND NAVY YARD.

REPORT OF A SPECIAL COMMISSION OF INVESTIGATION INSTITUTED BY "THE MEDICAL NEWS."

A FEW weeks since the public of Philadelphia was surprised to read in its daily press the statements, bearing official stamp, that League Island, for some time occupied as a naval station by the United States Government, is regarded by the department as unsanitary and a menace to health. Surgeon-General Tryon of the Navy has in several reports mentioned the bad sanitary conditions at the island, and indeed it would seem, from his report to the department, dated August 31, 1896, that in his opinion typhoid fever is almost endemic there. The "Massachusetts," commissioned at League Island in the past summer, had directly afterward several cases of typhoid fever among her personnel. I copy the following extracts from the report of Surgeon Seigfried of that ship:

". . . we have this day (August 31, 1896) transferred to hospital our fifth case of typhoid fever since going into commission at League Island Navy Yard, June 10th.

". . . the 'Indiana' which ship also commissioned at League Island, and in the following few months having had sixteen cases of typhoid fever (my informant being one of her medical officers), it is apparent that this matter of infection of new ships taking place at that station should be properly characterized and abated.

". . . very palpable and general sanitary evils and nuisances are evident at League Island, and particularly its approaches in one direction, extending for several miles on a direct road to the city. These evils are not readily or soon remediable and it is impossible for the personnel, whether ashore or on liberty, to avoid wholly the dangers of the city's water supply and sewerage difficulties, not to speak of the milk and fresh vegetable supplies. Our ship left the Delaware on August 5th. I recommended that fitting out of new ships at League Island be avoided until that section can be characterized as being clean and without its present uncivilized surroundings.

"In the summer of 1890 the United States marines at League Island experienced almost an epidemic of typhoid (my informant being one of their officers), and the 'Indiana's' experience following her commissioning there only last year was deplorable."

Following this Surgeon-General Tryon made a report to the department from which I extract these statements: "Results of recent investigations just received, relating to origin of cases of typhoid appearing on vessels in the vicinity of Philadelphia, corroborate the statement contained in the report of the surgeon of the 'Massachusetts.'" "Four cases appeared on board the 'Bancroft' during this summer's cruise, and Past-Assistant Surgeon McCormick, in a carefully prepared report and after thorough inquiry into possible sources of contamination, states he thinks it more than probable that the origin of the fever in the four cases was traceable to the drinking-water in Philadelphia, the water supply of which city is from the Schuylkill River which represents the drainage from a densely populated valley." "He further states that in his opinion the fever could not have originated from causes within the ship, the hygienic condition of which has been excellent throughout the cruise. In view of these facts there is little doubt of the origin of the disease, and that it is unavoidable so long as the present conditions exist. Unless there is decided improvement in the sanitation of this locality, naval vessels should be commissioned elsewhere if practicable."

While, in the majority of instances, it is exceptionally difficult to locate definitely the precise source of infection in an outbreak of typhoid fever, it is, I believe, generally conceded that in most cases the water or food supply is at fault; that there must be some manner of conveying to the human gastro-intestinal tract the specific germ of the disease, and that the medium generally selected is the water. Given one case of typhoid fever, especially of the ambulatory variety, situated in a group of men of necessity limited to crowded quarters, and it is easy to see how this one case, even under the usual sanitary precautions, may become the starting-point of an after-coming outbreak of the disease.

Without the sympathy and coöperation of the Navy Department a scientific demonstration of the sanitary conditions existent at League Island is, of course, impossible; but in view of the great importance, from a commercial as well as from a scientific standpoint, which the subject bears, a few facts and some semi-official information upon the matter may be of interest.

From its situation at the confluence of two such great rivers as the Delaware and the Schuylkill it might readily be supposed that League Island is an alluvial deposit; but though the island has a top stratum of alluvium, as shown by borings, it is actually a part of the main land, separated only by a narrow channel, which has been greatly deepened by dredging in late years. For over 150 years before its occupancy by the United States Government the island was laid out in fine farms, upon which grew dry meadow grasses, and from which came bountiful and unfailing crops. During that time, as now, its area of about 500 acres was protected from the water of high tides by embankments of earth and stone. Some idea of the fitness of its conditions for the purposes of a navy yard may be gained from the following extract from

the report of a commission of five United States naval officers, high in rank, appointed by the President in 1867 for the purpose of investigating the island and its surroundings. The commission "entered into a thorough personal examination of League Island and bestowed its careful consideration upon the relation of all the various points and details involved to present and future wants and purposes of the Navy of the United States, and, in respect to its adaptation for all purposes whatever, this board does not hesitate to recommend with entire unanimity that League Island be held for naval purposes by the United States." In 1864, Mr. Geo. Davidson, of the United States Coast Survey, conducted an investigation and made borings at League Island, and this report to the department contains the statement that the land is high enough for good drainage, and that the island had upon it about 250 large trees, some of which he estimated by cutting to be about 150 years old. His conclusions from borings made all over the island are as follows: A surface soil averaging about 3½ feet over the entire island; this is stiff, yellowish, clayey material. Beneath this is a stratum, with an average depth of twenty-five feet, of very fine sand, laminated with dark, clayey material, and under this a stratum of course sand, gravel, and boulders. It was Mr. Davidson's opinion that with such materials no piling would be necessary for buildings of the heaviest description.

The island was accepted by the Government in 1868, but building to any extent was not begun till 1873. It was found necessary to fill in the ground to be occupied by the buildings, and accordingly this has been done as was needed, and at present the entire part of the island upon which stand the heavy shops of the yard is of made ground. Work is being carried on now toward filling in a large area at the northern part, just east of the main road. The natural advantages of the island in special adaptation for the purposes of a naval yard are very great, in that it is surrounded by a body of water which is never even brackish, and which has sufficient depth for vessels of the largest size; that it is situate near the great coal and iron centers; that it can easily get supplies of men from a great city, and that it is difficult of access to a foreign nation.

From the Report of Surgeon-General Lyon for 1893 I take the following: "The general health of the island has been fair. The water supply is insufficient and dangerous. The Back Channel water is contaminated by the sewage from Philadelphia. The houses of the officers are very unsatisfactory in winter."

With these facts in mind I visited League Island, October 8th, for the purpose of determining officially or unofficially the existing conditions as far as possible. The barracks was situated on the main land upon the bank of the Back Channel, east side of Broad street, and have as a water supply for drinking and culinary purposes rain-water, which is collected from the roofs in five large sheet-iron tanks, entirely covered except for cap-protected man-holes for the water spout and for cleaning the tanks. The tanks appeared to be in good condition and there seems to be no reason why this water should not be as good as any water collected in clean cisterns or tanks. There is a driven well at the back of the barracks, but I was assured that this water was considered unfit for use and never used. I secured two bottles of the drinking-water which I drew directly from the tank in daily use by the marines. It had a pleasant taste; was clean, sweet, and odorless. The following is the result of an analysis of the specimen for chlorin and ammonia, which shows that these exist in proportions beyond the limit of waters characterized as "impure." For the purpose of comparison I give in connection with this the proportions of the same contaminations in the waters of New York, Boston, and in the Delaware and Schuylkill Rivers, as determined by Dr. J. H. Wright of Harvard.

Results in Parts in 1,000,000.

	Chlorin.	Free Ammon.	Alb. Ammon.	
New York.....	2.31	0.008	0.095	.....
Boston	3.70	0.005	0.161	.....
Schuylkill...	4.06	0.025	0.112	.....
Delaware.....	2.40	0.031	0.130	.....
Specimen from tank at Barracks of L. I..	85.245	0.358	0.1415.	Chemically Impure.

As to the source of contamination of this water, evidently very impure, chemically, I can only form conjectures. The iron tanks, in which it is collected, are in apparently good condition, but are sunk in the ground within six inches of their tops, and may be faulty in construction, letting in contamination from the outside. Such relatively large quantities of chlorin and ammonia are, of course, only indicators of the quality of the water, of which, it would seem, a careful analysis, chemical and bacteriological, is imperative.

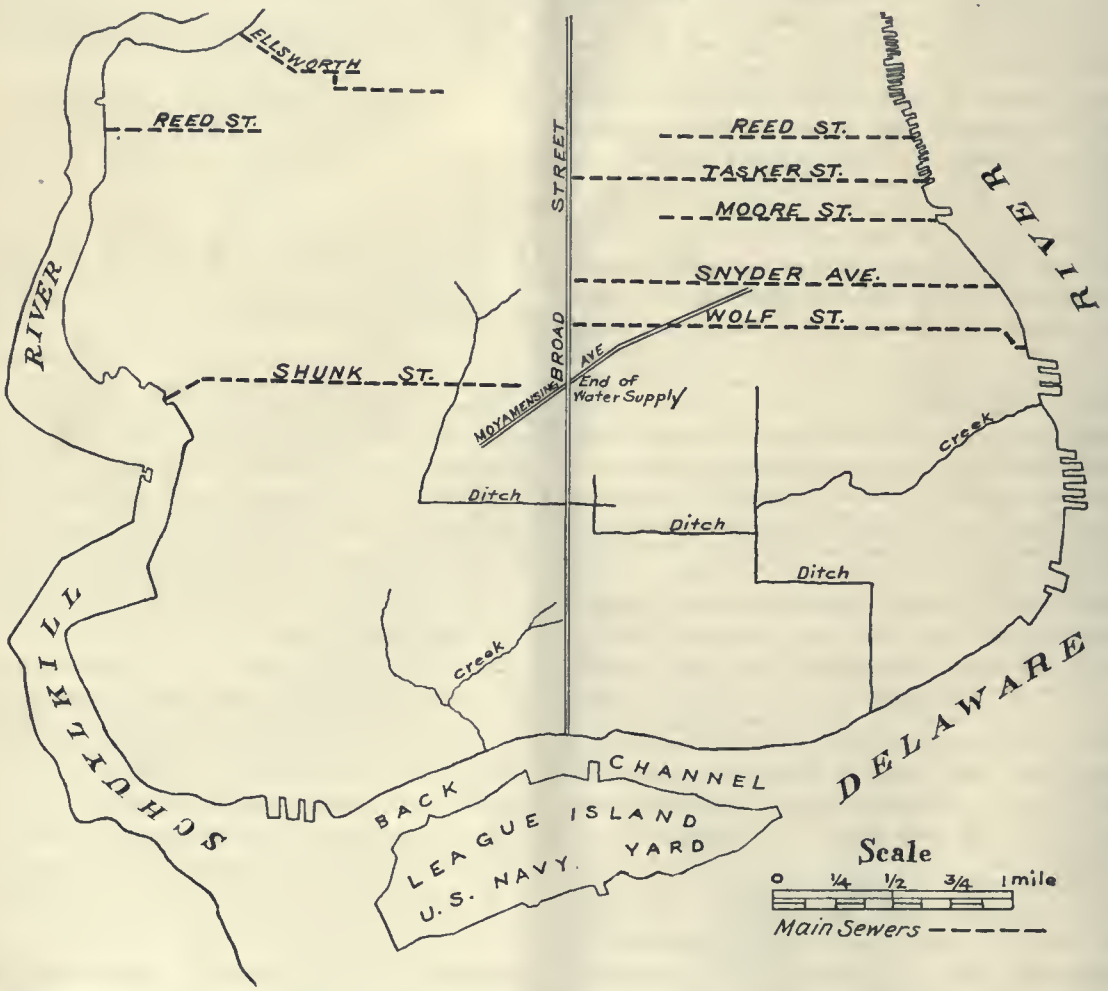
The corporal of the guard, and others of the marines, told me the drinking-water was satisfactory, and said that there was very little sickness at the barracks. About one hundred yards back of the barracks, and overhanging the water of the Back Channel, are the urinals; at this point the tides cause a swift current in the channel.

On the island, among the employés of the Navy Yard, the invariable report was that the island was healthy and that their drinking-water also—rain-water collected in large iron tanks from the roofs—was excellent. At the wharf the working men said they drank the Delaware River water on very rare occasions, while in the dry dock, when dry, a spring of water gushes through the timber flooring, but this, as one of the officers informed me, is considered to be due to the pressure of the water outside the dock, and the spring-water is of such disagreeable taste as to be unfit for drinking purposes. Upon the recruit-ship the water used for drinking and culinary purposes is condensed from the boilers. In the summer time, I was told by an officer of the ship, occasionally water was furnished this ship by a supply-boat from Philadelphia, but such water is never accepted until tested and approved by the surgeon of the ship. The drinking-water supply of ships stationed at the island is from the condensing tanks of these ships. The large

machine-shops and the houses of the Captain and Surgeon of the Yard are provided with large tanks for collecting water, as are also the few farm-houses upon the island. There are no wells upon the island, though at the present time an artesian well is being sunk, the intention being (as one of the officers informed me) to go to the depth of 800 feet. The iron staging for a large tank of the capacity of 30,000 gallons is in process of erection near the artesian well, and from this source water will be conducted to all parts of the island. There is a system of pipes running near the buildings and into these water

complement of about 350 men, officers and employés, they have little sickness on the island; that they average from ten to twelve cases of malaria in the year, while there has been only one case of typhoid fever on the island since 1890, and that the typhoid cases of the "Massachusetts" were undoubtedly imported from other ships or stations.

The accompanying map, which is drawn to scale, shows the relation of League Island to the southern portion of Philadelphia, which is called the "Neck," and is a district very sparsely populated. Here it will be noted that the city's water supply extends no farther southward



Plan of the lower portion of Philadelphia, showing sewage system of that portion of the city, the nearest point of the water supply, and the relation of these to League Island.

can be pumped from the Delaware River for fire purposes, flushing the sewers, etc. The Captain of the Yard, Ship's Surgeon, and the other officers, with whom I talked, received me very courteously, but regretted that a regulation of the Department would not permit them to discuss the question with me. However, incidentally in conversation with them I learned, in addition to the facts I have enumerated, that the island is considered to be an ideal place for the location of a naval station; that the drainage system is fairly good; that with an average

(toward League Island) than the junction of Broad street and Moyamensing avenue — a distance of over two miles from League Island—and at about this point also is the southern limit of the city's sewers, while the sewers empty into the rivers on either side at a distance above League Island very considerably greater than two miles. The large portion of the Neck is on a level below that of the high-tide mark, and is protected from inundation by embankments at the river edge. The water in the ditches and creeks rises and

falls with the tides, and though the ditch-water is often used for cooking purposes by the residents, the main source of drinking-water in this portion of the city is from tanks of rain-water.

The health of the community is remarkably good. Dr. Wm. R. Read of 1403 South Broad street has been in practice twenty-five years and attends a number of families in the southern portion of the city. He has never seen a case of malaria or typhoid in the Neck. Dr. G. H. Meezer, 1425 South Broad street, in a practice of twenty years, says he has never seen a typhoid case anywhere near League Island, while malaria is rare in that district. Dr. C. A. Usilton, Ninth and Dickenson streets, has had a large practice in lower Philadelphia since 1882, and has never seen a case of typhoid fever or malaria in the district. These three gentlemen consider it a very healthy locality, with some remarkable cases of longevity. In their belief, the cases of typhoid occurring on board the ships stationed at League Island were undoubtedly imported.

Surgeon Seigfried, in his report, makes reference to an epidemic state of typhoid at the island in 1890. Although the annual reports of the Surgeon-General of the Navy have for a number of years been most meager as to details of sanitary conditions, I find this in the report of 1890: "All navy yards and stations: Febris enterica, five cases; three sent to hospital; no death."

The report of 1893 says of League Island: "General health, fair. During June and July there was an outbreak of diarrhea at the barracks, which, however, quickly subsided. The cause was probably heat and humidity, for people living outside the yard were similarly affected." Perhaps the surgeon of the "Massachusetts" had reference to this year, instead of 1890.

In conclusion, and in absence of accurate scientific data to the contrary, I think it reasonable to believe that League Island is in a very fair condition as to health, and that if typhoid cases appeared upon the ships stationed at the island, they were brought there from some less healthy locality. One supreme drawback to the island as a naval yard or station is, I am told, its inaccessible position in relation to Philadelphia. It is about four miles from the heart of the city, and, as the "'busses" which run during the day stop at 7.00 P.M., the traveler bound for the island after that hour, whether on business or pleasure bent, must take a cab or walk.

HERBERT R. GOODRICH, M.D.

PHILADELPHIA, PA.,
October 12, 1896.

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Ninth Annual Meeting, held in Richmond, Va., September 22, 23, and 24, 1896.

FIRST DAY—MORNING SESSION.

THE Association met at the Jefferson Hotel, and was called to order at 10 A.M. by the President, DR. JOSEPH PRICE of Philadelphia.

After the usual preliminary exercises, the reading of papers was proceeded with.

JOHN M. DUFF, M.D., of Pittsburg, read a paper entitled

PELVIC DISEASES AND THEIR PRINCIPAL CAUSES; WHAT SHOULD THE LAITY BE TAUGHT CONCERNING THEM?

That at this day, through mistaken diagnosis, operations are sometimes needlessly performed, no one would have the hardihood to deny; but that such cases are as frequent as some critics say they are, he could not believe. The true pelvic surgeon was governed by nobler purposes, by more elevated aims. Conservatism in its true sense—the saving of life, relief from pain, the curing of the patient, was his watchword.

WALTER B. DORSETT, M.D., of St. Louis, followed with a paper on

DECEPTIVE SIMILARITY OF SIGNS AND SYMPTOMS OF INTRA-ABDOMINAL DISEASE, WITH CASES.

The exploratory incision should not be regarded as an evidence of ignorance, but as a legitimate means of diagnosis, and the off-hand diagnostician or the surgeon who never makes mistakes should be looked upon with at least a grain of suspicion. Three interesting cases were reported, one of which is here given:

Mrs. M., aged twenty-eight, married eight years, no pregnancies, was seen by him about a week after having recovered from an attack of malarial fever. Temperature, 99°; pulse, 90; tongue slightly coated and a tendency toward diarrhea. Complained of general abdominal tenderness. Palpation of abdomen revealed a slightly more tender spot at McBurney's point; no swelling or tumefaction could be felt. A vaginal examination revealed a retroversion with fixation; no tubal enlargement nor tenderness could be made out; no vaginal discharge. Diagnosis: Gastro-intestinal irritation, with chronic inflammation of pelvic contents. Diarrheal mixture was prescribed, and patient was told that further attendance would probably not be necessary. Four days subsequently the temperature was 99.8° F.; pulse, 100. Abdominal palpation revealed a distinctly tender spot, with some swelling, at McBurney's point. Patient stated that she had eaten heartily of Wienerwurst the day before, and had been awakened during the night by cramps at the navel. Bimanual examination was again resorted to, with negative result. Appendicitis was diagnosticated at this visit (first stage). Dram doses of salts were prescribed, and patient was urged to go to the hospital, but refused. The next day she was seen, and found sitting in a rocking-chair; and, aside from slight tenderness over abdomen, was feeling quite comfortable. Salts had acted freely. Bimanual examination again gave negative results. Temperature, 99°; pulse, 100. Patient was ordered to bed and advised to keep quiet. The case was regarded as better, and thought to be out of danger. The following day the pain became more severe, and the patient came to the hospital of her own accord. Upon examination, the right iliac fossa was found to be exceedingly tender and fluctuating. Vaginal examination revealed nothing,

aside from what was found at the previous examination. Temperature, 103; pulse, 130. Diagnosis: Ruptured appendiceal abscess. She was anesthetized and placed upon the table, and a section made in the median line. The large sac was found on the right side, filled with fluid blood and clots, and when washed out, a rent of the posterior layer of the broad ligament was found, which communicated with another rent in the Fallopian tube. Appendix appeared healthy, and was not disturbed. A thorough washing out of the sac was done and ligation of the tube, with a portion of the broad ligament. A glass drainage-tube was introduced. Notwithstanding the utmost care, the temperature remained high, pulse became worse, the abdomen became distended, and patient died on the third day. Post-operative diagnosis: Ruptured tubal pregnancy, without the usual symptoms. There was no history of shock, no cessation of menstruation, nor nervous symptoms of pregnancy. No passage of decidua, no vaginal discharge of any kind, but in its stead a good history and train of signs and symptoms of inflammatory disease of the appendix.

RUFUS B. HALL, M.D., of Cincinnati, Ohio, read a paper on

THE MOST POTENT CAUSES OF PELVIC INFLAMMATION.

He claimed that septic infection, following labor or abortion, or gonorrheal infection, was the cause in almost every instance. The most frequent cause, he believes to be gonorrheal infection conveyed to the woman from a latent gonorrhea of her husband. The more he sees of the ravages of gonorrhea, the more he is convinced of the fact that the profession is derelict in its duty to its patients in the dissemination of knowledge upon this subject. He has, on many occasions, been compelled to remove suppurating tubes and ovaries from women who had contracted the disease from husbands who believed themselves well when married. He has no hesitation in asserting that gonorrhea is more destructive to women than syphilis. No man has a right to marry until the irritating injections show the absence of gonococci in the discharge—frequently a period of two years after the beginning of acute symptoms—otherwise he will certainly infect his wife. If the profession would advocate and practise this doctrine, we would right many of the existing wrongs inflicted upon innocent women.

Dr. Hall is a firm believer in legislation upon this subject. He believes every man should have a certificate from the health officer of freedom from syphilis and gonorrhea before he is granted a marriage license. Until this is enacted, the parents of the bride should demand from the prospective groom a certificate of freedom from venereal disease, by a physician of their selection. If this could be brought about, there would be no necessity for fully one-half of the sections now made, and a corresponding amount of suffering, both mental and physical, would be obviated.

DR. J. HENRY CARSTENS of Detroit, in discussing the three preceding papers, said that when prominent ministers of churches consulted physicians and asked them to produce abortion on their wives, he became discouraged, and thought it was love's labor lost. Still, the gynecologist should keep on preaching against the evils attending the production of abortion.

Regarding Dr. Dorsett's paper, the too frequent opening of the abdomen stimulated incompetents to do likewise, and, as a consequence, results were disastrous, eventually reacting on gynecologists.

DR. W. E. B. DAVIS of Birmingham, Ala., does not believe that gonorrhea plays so important a part in the production of pelvic inflammation as was heretofore taught. Fully fifty per cent. of the cases of pelvic inflammation are due to puerperal infection, either at the time of delivery at full term, or premature delivery. More importance is being attached to tubercular trouble as a cause of pelvic inflammation than it deserves.

DR. JAMES MCFADDEN GASTON of Atlanta (by invitation) said that extreme hygienic precautions might warrant, in some instances, the use of antiseptic washes prior to labor, but nature should be allowed to take its course, unless there were ample reasons for interference.

DR. ERNEST S. LEWIS of New Orleans operated on a patient, last winter, for what he supposed at the time was a small ovarian tumor, but, after the abdomen was opened, it turned out to be a retroverted gravid uterus.

DR. F. D. THOMPSON of Fort Worth, Tex., would like the essayists to have gone more fully into the point as to when it was safe for men who had been the subjects of gonorrhea to marry and have intercourse with their wives. Many cases of gonorrhea occurred in married men, and the gynecologist had before him all the ills and consequences incident to this disease. How long shall such men abstain from sexual intercourse? These points should be dealt with more fully and explicitly.

DR. LEWIS S. MCMURTRY of Louisville considered the view enunciated by Dr. Hall as to gonorrhea and its relations to marriage impracticable. The exploratory incision for diagnostic purposes should be sufficiently large to enable the surgeon to explore thoroughly the abdominal cavity.

DR. E. F. FISH of Milwaukee recalled one case in which an exploratory operation saved the patient's life.

DR. RICHARD H. GIBBONS of New York, thought many of the cases dealt with in the papers were due to puerperal contamination, or, in some instances, to laceration of the cervix, as had been pointed out by Emmett. He believes that Noeggerath gave us the keynote to the class of infection produced by gonorrhea. Relative to diagnosticating intra-abdominal diseases, there was no particular symptom that was pathognomonic.

DR. HOWARD W. LONGYEAR of Detroit believes the teachers of the public schools should be empowered to impart the necessary knowledge regarding the dangers of gonorrhea and its consequences.

DR. GEO. BEN. JOHNSON of Richmond presented the specimen of an ovarian tumor, the first one removed under Listerism in the State of Virginia, so far as he had been able to ascertain. The patient was an unmarried woman, twenty-six years of age. The tumor was removed March 19, 1879. The tumor, with the sac and fluid contents,

weighed thirty-four pounds. The operation was performed under the spray and with the elaborate dressings recommended by Lister. The patient died, however from sepsis. In November of the same year he was consulted by Mrs. M., whom he presented to the Association, for what turned out to be an enormous unilocular ovarian tumor. Her measurements were six feet and four inches around the abdomen at the umbilicus, and three feet and two inches from the ensiform cartilage to the pubes. The contents of the tumor and the sac weighed ninety-six pounds. This operation was performed at the patient's house, with the same care as that of the previous one. Recovery.

Albert Goldspohn, M.D., of Chicago read a paper on

TUBO-OVARIAN CYSTS, WITH INTERESTING CASES.

In order to exclude a large number of ordinary tubo-ovarian conglomerates, we need to recognize the following minimum requirements in distinguishing a tubo-ovarian cyst: (1) The participation of the tube, which is easy enough from its position and connections. (2) To prove the participation of the ovary by demonstrating some ovarian tissues in the wall of the sac. (3) That their cavities are united by some opening through which the mucous membrane of the tube is continuous with the lining of the ovarian cyst or follicle. Applying this standard, the author has been compelled to exclude a number of cases that have been mentioned as such cysts, because the three points were not proven in each of the three cases. The total number of authenticated cases that the author has been able to find in literature is thirty-eight, by twenty-five different authors. His conclusions were as follows: (1) Tubo-ovarian cysts arise in consequence of a plastic inflammatory union between a Fallopian tube and the adjacent ovary, after either or both of these organs and the intervening peritoneum have experienced a non-purulent pathological change of a cystic character. The septum intervening between the two lumina disappearing in consequence of pressure-atrophy from the tension of liquid confined to one or both sides of it. (2) This union of a distended tube-cavity may occur also with that of a parovarian cyst (v. Ott), or with that of a peritoneal pseudo-cyst (Zedel). (3) In those rarer cases in which the fimbriæ are really found floating in the interior of the main cyst-cavity, we must assume either the congenital anomaly of an "ovarian tube," as was seen by Schneidemahl in a mare, as a vitium primum formationis, or that an ovarian cyst or follicle-cyst ruptured, and the abdominal end of the tube dropped into the rent and was united to its edges by inflammatory action, thus making a joint cyst and tubal cavity.

Walter B. Chase, M.D., of Brooklyn, read a paper on

MIXED TUMORS OF THE OVARY.

These tumors of the ovary may be made up of a variety of cysts, or may be a combination of cysts and solid growths. Retention-cysts of the ovary are not tumors in a technical sense, and are never large. Large ovarian cysts are most often cyst-adenomas, and are not developed from Graafian follicles, but arise from the embryonic structure. The case reported, operated upon by the author at St. John's Hospital, August 4, 1894, was a mixed tumor of the left ovary, consisting of a large cyst-adenoma, containing about two gallons of clear, straw-colored fluid, a dermoid intimately united with the cyst-adenoma, containing less than a quart of fluid, leaving true bony plates in its wall, and numerous encysted papillomas encrusted within the walls of both cysts.

(To be continued.)

SECOND INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS.

Held at Geneva August 31 to September 5, 1896.

(Concluded.)

HYSTERECTOMY.

Dr. Paul Reynier of Paris referred to the danger of intestinal adhesions after hysterectomy, often a result, in his opinion, of septic processes. The practice of stuffing the vagina with iodoform gauze, except for hemorrhage, is a bad one, for adhesions with the intestine often result, and when the gauze is drawn out the intestinal coils are pulled into the upper vaginal orifice. If the intestine is inclined to prolapse it is better to close the peritoneal opening with suture or clamps, before introducing the gauze.

Dr. Delangeouiere of Mons presented a third series of abdominal hysterectomies for fibro-myomata. He mentioned certain improvements in technic.

The vagina and cervix are to be considered part of the operative field, and are to be sponged with iodoform gauze, and then cleaned with a one per cent. alcohol solution of bichlorid of mercury, and an aqueous solution of bichlorid of mercury of the same strength, followed by a light tampon of gauze.

For the final hemostasis, four pedicles are made corresponding to the arterial supply. A silk thread is passed through the vaginal wall, about the uterine artery. The utero-ovarian artery is included in a horizontal pedicle at the level of the vaginal reflection—just as in an oöphorectomy. The bleeding of the vaginal margin is stopped by three sutures placed in front and behind, and drawing together the cut surfaces—as a final precaution the edges of peritoneum are stitched together. Drainage is a good thing. No drain is left in place more than forty-eight hours. A frequently renewed tampon, and, later, antiseptic injections, are advisable.

VAGINAL HYSTERECTOMY IN IRREDUCIBLE INVERSION AFTER CHILDBIRTH.

Dr. Duret of Lille spoke of the difficulty of locating the incision in these cases, as the cervix is obliterated. Palpation is of some assistance. Seizing the neck of the tumor between thumb and finger, it is possible to make out by its thickness where the cervix begins, and the incision is made above this line, care being taken to avoid the contents of the infundibulum and the vessels. In fact, as soon as a transverse incision has been made anteriorly into the peritoneal cavity, it is better to complete the hysterectomy by means of a median incision. This starts from the transverse vaginal incision and splits the anterior wall of the uterus into a right and left half. The

adnexa are then easily seen, and may be ligated if desired. Next the uterus is raised and the posterior cul-de-sac transversely incised. The uterine arteries are ligated from the vagina, and the lateral ligaments are clamped. The median division of the uterus is then completed, the adnexa drawn down and ligated, and removed with the uterus.

SURGICAL TREATMENT OF RETRODEVIATIONS OF THE UTERUS.

DR. POZZI'S conclusions were as follows:

All surgical treatment whose object is to fix the uterus by attachment to a limited area of its surface can have only temporary results. Constant traction upon the point of artificial attachment will in time produce again the displacement. This explains why Alexander's operation, and vagino- and vesico-fixation, give the uterus only a temporary stability, and, besides, many of these operations ought to be rejected because they are a real source of danger in future child-bearing.

The rational treatment of excessive mobility of the uterus (movable retrodeviation) may be expressed as follows, according to individual conditions: (*a*) Cure the metritis which so often exists by curettage, amputation of the cervix, etc. (*b*) Restore the perineum, if torn, by a suitable lactic operation. (*c*) Fit the patient with a pessary which, by distending the posterior cul-de-sac, holds the cervix in position; and regulate the intra-abdominal pressure by an abdominal belt.

In fixed retrodeviation of the uterus the principal lesion is not the displacement, nor the adhesions, but the diseased condition of the uterus, tubes, and ovaries; and treatment is to be chosen accordingly.

In many cases the trouble in the adnexa is secondary to that of the uterus, and passes away if the latter is properly treated; in others, the lesions in the adnexa are primary, and the metritis secondary. In such cases laparotomy is indicated, and if the trouble is of a mild character, such as cystic disease of the ovary without occlusion of the tubes ignipuncture or partial resection of the ovary is to be performed. After adhesions are destroyed the uterus will right itself, but for safety it may be stitched to the abdominal wall. If the tubes are obliterated, and the ovaries more or less diseased, castration is the suitable operation; and by this means the symptoms, often falsely attributed to the uterine displacement, will be cured.

Vaginal hysterectomy is preferable in the presence of old bilateral lesions of the adnexa, with chronic metritis and hypertrophy of the uterus.

DR. KASTNER of Dorpat, discussing the same topic, drew the following conclusions:

The operative treatment of retroversion and retroflexion by holding the uterus in a forced anterior position prevents the formation of adhesions and ultimate prolapse, and reëstablishes, to a certain degree, the mobility of the uterus and its pelvic relations. In immobile retrodeviations massage and Schulz's operation are to be employed, and laparotomy is indicated only if very strong adhesions exist. Abdominal section is, for this purpose, more exact, and allows of a more thorough treatment than either anterior or posterior colpotomy. Abdominal, abdomino-vesical and vaginal fixation and Alexander's operation keep the uterus in a good position, which is not true of certain recently devised procedures, such as Sänger's retrofixation. Ventral and vesical fixation and Alexander's operation do not disturb the normal functions of the uterus. Vaginal fixation is not to be performed in women liable to bear children. If a tendency to prolapse exists the colporrhaphies should be combined with vaginal fixation. If adhesions are extensive laparotomy should be performed, the adhesions broken up, and the uterus fixed to the abdominal wall. If the adnexa are diseased they are to be removed in part or altogether; but the advantage here of conservatism is never to be lost sight of. Curetting, baths, and other forms of symptomatic treatment are seldom advisable. Alexander's is the best operation for mobile retrofixation and retroversion, because it most nearly restores the parts to their normal position.

Indications for operative treatment are immobile retrodeviations, or lack of success with pessaries, or a deformation of the vagina, which prevents their employment.

As prolapse is usually secondary to retroflexion or retroversion of the uterus, any operation for its relief ought to reëstablish the anterior position of the uterus. Hence the advisability of combining anterofixation of the uterus with the plastic operations designed to narrow the vagina.

DR. POLK of New York expressed himself as opposed to the fixation of the body of a retrodeviated uterus if the patient is still capable of becoming pregnant. He prefers Alexander's operation, supplemented, if need be, by shortening of the utero-sacral ligaments, through a vaginal incision. If adhesions are present, they are first to be broken up. This is also the proper treatment for a retrodeviated uterus in a patient from whom tubes and ovaries have been previously removed, and also for retrodeviation occurring after the menopause. These operations are performed as follows: The anterior vaginal vault is incised, the uterus and adnexa freed from adhesions, if such exist. The uterus is anteverted, and its fundus drawn into the vagina. A silk suture is passed about the round ligament with its peritoneal investment far enough from the uterus to permit the sutured portion to be brought easily to the attachment of the ligament at the uterus. The loop thus made is sutured together and returned to the round ligament beyond the point of reduplication. The procedure is repeated on the opposite side and the vaginal opening is closed. In order to shorten the utero-sacral ligaments, a transverse incision is made in the posterior cul-de-sac, and a silk ligature is passed through the ligament at about its middle, and then through the tissue at the junction of the vagina with the cervix. The ends of each suture are brought through into the vagina, tightly knotted, and left long until both are in position and ready for tightening. When the sutures are tightened the ligaments are doubled upon themselves, and by this means the cervix is pulled backward and upward. The cul-de-sac is closed with catgut. The drain is taken out in two weeks, but the patient must not get up for three weeks.

Dr. Péan of Paris drew these conclusions from his practice:

Mobile retrodeviations are to be treated by pessaries with a hard surface, permitting cleaning, such as aluminum has. The necessary plastic operations should precede their application.

If recent or light adhesions are present, mobility should be secured as soon as possible by medicinal means. If these fail, Sims' articulated repositor or Brandt's massage should be tried.

When the adhesions are so firm that they will not give way, the finger should be introduced into Douglas' cul-de-sac, the territory explored, and any adhesions broken up, and small tumors of the tubes or ovaries removed.

If, in spite of all care, the pains continue, in order to prevent a relapse, the uterus should be fixed anteriorly, preferably by freshening its anterior surface and that of the bladder, and suturing the two.

If the uterus is bound down so firmly that it cannot be replaced, conservative treatment is inadvisable, as the lesions are certain to have affected tubes and ovaries to such an extent that complete castration is the only allowable operation.

Dr. Jacobs of Brussels reported that he had had better results with anterior vaginal fixation than with abdominal fixation.

Dr. Kummer of Geneva reported twenty-two patients with uterine deviation, combined in several instances with prolapse of different degrees, upon whom he had performed Alexander's operation with gratifying results. Only one case relapsed.

Dr. Chaleix-Vivie has learned from the examination of a great many women who have submitted to operations for retroversion that the restoration of the uterus, if unaccompanied by other treatment, is followed by a cure in comparatively few cases; and that it is equally important, to dilate and curette in endometritis, to amputate a diseased cervix, and to restore a distorted vagina and perineum.

Dr. Otto Engstrom favors ventrofixation when surgical interference is necessary. He uses a single suture including the peritoneum and base of the uterus, removing it on the fourteenth day. This fixation becomes peritoneal and elastic, and gives the uterus almost a normal mobility.

Dr. Mangin of Marseilles summed up the treatment employed by him: the pessary in movable retrodeviations, and if it is not well borne vaginal colpohysteropexy with any necessary vaginal plastic operations. Alexander's operation and ventrofixation he reserved for patients with lax tissues. In complicated deviations he seeks to reduce the conditions to simple ones by medical treatment, and then to apply the above rules. If the adnexa are seriously involved his rule is to perform laparotomy for unilateral lesions and hysterectomy for bilateral ones.

Influence of Coccygeal Mobility upon Retrodeviation.—Coccygectomy.

Dr. Blondel of Paris insisted upon the importance of the coccyx in backward displacements. He said that abnormal mobility of this bone, resulting from traumatism, or more often from childbirth, allowed a displacement forward of the anus and vagina of an inch or more with the formation of a posterior colpocele and retrodeviation. This condition may or may not be accompanied with coccygeal pain. A very long Hodge pessary or a posterior colporrhaphy may give some relief, but if there is much pain and removal of the adnexa is not formally indicated, he counsels a coccygectomy with suture of the levator ani to the sacrum. The operation is in no wise dangerous, and if successfully accomplished it cures the retrodeviation by driving backward and upward the cervix.

Dr. Stapfer of Paris spoke of the excellent results he had obtained by massage and gymnastics, and expressed his appreciation of massage as a means of diagnosis.

Dr. Boyer of Paris claimed that massage can relieve the pain even though the uterus remain in a false position.

Dr. Chamain of Paris thought electricity was indicated in all recent movable retrodeviations, combined with appropriate hygienic and medical treatment, and preceded if need be by mechanical treatment, especially taxis. He employs the continuous current with the positive pole in the uterus, and the negative pole on the lower abdomen and large enough to reach both groins—or the faradic current with a double external electrode, one over each inguinal region, and frequently alternating the current. Static electricity is also used. In any case vigorous asepsis is observed.

The meeting of September 3d was opened with discussions on

The Best Method of Closing the Abdomen.

Dr. Granville Bantock of London finds the simple suture sufficient in the majority of cases. When the patient is very thin or very fat the peritoneum ought to be first closed by a continuous suture, and afterward the rest of the abdomen may be closed by ordinary sutures in one or two layers. For interrupted sutures he considers silkworm-gut the best; catgut for the deep sutures.

Dr. F. la Torre of Rome spoke of the frequency of hernia when the extraperitoneal method of closing the abdomen was used. A section made on the *linea alba* is often the cause of hernias. These do not generally follow when the section is made in the muscle itself; silk, catgut, silkworm-gut and silver wire are usually employed; however, the author prefers silk or catgut. The best method is that in several layers, and preference is given to a continuous suture in the peritoneum.

Dr. Byford of Chicago spoke of the imperfect coaptation and infection as causes of post-operatory hernias; he employs the following method: A certain number of buried sutures of silkworm-gut (three cm. apart) are placed in layers, comprising the muscular layer, the aponeurosis, and the peritoneum; before fastening these sutures he puts a few sutures (one cm. apart) through the entire thickness of the abdominal wall. The majority of hernias in his cases occur after several years, espe-

cially in cases where he had employed prolonged drainage. In cases of laparotomy, requiring only an incision below the umbilicus, he cuts directly in the muscle alongside of the *linea alba;* on the other hand, when the incision is to be long, and when the abdominal wall is distended and thinned by a tumor, he recommends resection of the *linea alba*.

Dr. Alban-Doran of London thought that two years must elapse before the danger of hernia is past. His sutures are about the same as those of Dr. Granville Bantock. Hernias, he said, are often due to the carelessness of the patients who do not wear their bandages for a long enough time.

Dr. Rapin of Lausanne spoke of the importance of having the suture line show as little as possible, especially in the case of young women. To obviate this he recommends horizontal incision, concave upward, three or four cm. above the symphisis pubis; this incision cuts through the skin, and the adipose tissue, as far as the aponeurosis, and fastens the upper flap with a provisional suture a little below the umbilicus. Then he makes a vertical incision (four to eight cm.) in the middle line through the aponeurosis muscles and the peritoneum. The wound is closed in three different layers. He removes the skin sutures on the third day in order to prevent any scars.

Dr. Kummer of Geneva in his experiments on animals always had more hernias in the case of *simple* sutures, than when he employed silk sutures in layers.

Dr. Jayle of Paris employes catgut for the peritoneum and muscles, and buried silk sutures for the skin, and two or three silk sutures, comprising the skin, cellular tissue, and the aponeurosis.

Dr. Vengstrom of Helsingfors passes silk sutures through the entire thickness of the abdominal wall, but before fastening them, sutures with catgut the peritoneum and the aponeurosis. He lays great stress on not fastening the sutures too tightly.

OBSTETRIC SESSION.

In the obstetric wing of the Congress reports were presented upon the relative frequency and the most common forms of pelvic narrowness in different countries.

The session of September 5th was opened by a discussion on the

TREATMENT OF ECLAMPSIA.

Dr. Charpentier of Paris emphasized the importance of examining the urine of pregnant women. If the slightest trace of albumin be found a milk diet should be ordered. This is the preventive treatment par excellence for eclampsia. In cases of edema without albuminous urine a milk diet is advantageous if not absolutely necessary. If the eclamptic patient is strong and very cyanosed, from 300 to 500 grams of blood may be taken. Then follows the administration of chloral. Chloroform inhalations will mitigate the convulsions, and injections of artificial serum will bring about diuresis. If there is no well-marked cyanosis, and the convulsions are infrequent, treatment may be restricted to chloral. If the contractions are too feeble or slow, the case must be terminated by version or forceps if the child is living; by cephalotomy, basiotripsy, or cranioclasy if the child is dead. Labor should rarely be induced. Cæsarean section and *accouchement forcé* are only to be resorted to in the most extreme cases.

Dr. F. Halbertsma of Utrecht considers active intervention necessary, when the prognosis seems extremely grave on account of complete anuria, or of the frequency and intensity of the convulsions, when there is no indication of labor, or when labor may be expected to be long and difficult, as in primiparæ and multiple pregnancies.

Dr. Veit of Leyden finds a mixed treatment gives the best results: Hasten labor prudently; rupture the membranes and deliver the patient after complete dilatation of the soft parts, give strong doses of morphin to lessen the number of convulsions, avoid oral administration of medicine to unconscious patients, produce diaphoresis by external means.

Dr. Byers of Belfort said that hypodermic injections of morphin should be administered at the onset of the convulsion. Care should be taken that fluid does not enter the lungs. Pulmonary edema is a common cause of death in eclampsia. The patient should be kept warm and purged freely. She should be given no liquid, and according as she is conscious or not between the attacks a warm or vapor bath. If labor has not begun the convulsions should be treated, care being taken not to excite the uterus to action. Chloroform should be given after labor has begun.

REVIEWS.

Food in Health and Disease. By I. Burney Yeo, M.D., F.R.C.P., Professor of Therapeutics in King's College, London. New (2d) edition. In one 12mo. volume of 592 pages, with 4 engravings. Cloth, $2.50. Lea Brothers & Co., publishers, Philadelphia and New York. 1896.

This is a very excellent handbook, divided into two very nearly equal parts; the first is devoted to "Food in Health," the second to "Food in Disease." In the first part the author takes up the various classes of food, questions of digestion and assimilation, preparation, dietaries, food for special periods, and finally the relative advantages of animal and vegetable foods. The remainder of the book is occupied with the problems of diet in different diseases and morbid conditions, not omitting the various "cures," and artificial alimentation. The three appendices contain hospital dietaries, sterilization and Pasteurization of milk, and select recipes, respectively. The importance of the subject, the industry of the author, and the usually indefinite notions of the average physician, render this contribution both a necessary and useful one. The author could well rest his reputation upon his most excellent "Manual of Medical Treatment," but he has enhanced it by his scientific and scholarly handling of the question of food. For its convenience in size, and the practical and sound advice therein contained, this should be the daily companion of the physician. Its success is assured.

ORIGINAL ARTICLES.

SOME GLYCOSURIC DERMATOSES.[1]

BY CHARLES W. ALLEN, M.D.,
OF NEW YORK;
LATE SURGEON TO THE CITY HOSPITAL AND DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITALS.

THE whole class of cutaneous eruptions, symptomatic of the presence of sugar in the urine, has been given by the French the title of *diabétides*.

If the dermatoses included under this designation were in the main pathognomonic of the underlying condition which their presence suggests, or if indeed there were sufficient characteristics to distinguish the diabetic eruptions from those of a similar nature, but of distinct etiology, the term might well take its place alongside of the syphilids, the scrofulids, the tuberculids, and the leprids.

The chief objection which I have to interpose is that many of the skin-manifestations of the sugar-disease often occur in the presence of the symptom glycosuria, which should not be confounded with the disease diabetes, and hence, as applied to these particular outbreaks, the term would be a misnomer.

It is so well known that the condition furunculosis coexists and frequently depends upon the abnormal presence of sugar in the system, that many, like myself, make it a routine practise to examine the urine in all cases showing, what we may term, the furuncular diathesis. This has, in many instances, led to the early discovery of glycosuria, and pointed out the way by which we may put an end to the otherwise persistent and obstinate complaint, *viz.*, by the reduction or possible cure of this sugar loss.

It has been claimed that in some instances, a furuncular process, having its origin in the skin, reacts upon the glycogenic functions secondarily, and is a cause rather than an effect. Whether this be so or not, we do see cases in which a glycosuria coincides with an outbreak of furuncles, and disappears when the boils cease cropping out. To my mind, both conditions here depend upon a common cause, and this cause being once removed, both manifestations naturally cease together.

[1] Read at the meeting of the American Dermatological Association, September 8, 1896.

I recall in this connection the following case, referred to me by Dr. W. T. Kudlich of Hoboken, N. J. :

Mr. C. was first seen by me on January 18, 1890. For several weeks the patient had had a succession of boils upon the back of the neck, followed by others upon the face. Upon examining the urine, I found it to contain a small percentage of sugar. The family history pointed to no instance of diabetes, but the personal history strongly suggested a cause for such a glycosuria, in that the patient consumed daily large quantities of champagne. The treatment consisted principally in withholding this and other sugar-bearing beverages and in ordering a rather restricted diet. The sulphid of calcium was given in dose of one-twentieth of a grain every two hours.

On January 27th, nine days after treatment was begun, all trace of sugar and all furuncles had disappeared. The patient remained under observation for a short time longer, on account of an erythematous eczema of the scalp and forehead, undoubtedly due to the same cause, and has since then remained free from any manifestations of the sugar-disease.

Carbuncle is another common skin-affection which should direct our attention to the urine.

I have at the present time under treatment a lady, who six years ago had a carbuncle on the back of the neck. The urine was not examined at that time, but there is a history of subsequent ill health which suggests that the disease diabetes had already begun at that time. About a year later, during an attack of grippe, the lady read of the death of the Khedive of Egypt, which was attributed to diabetes resulting from la grippe, and told her physician she felt sure that this was her own trouble. He examined a specimen of urine and found the patient's surmise well founded. This lady has always believed her diabetes originated from the grippe. I am equally convinced that it began at or before the time of the carbuncle and that, if looked for, sugar could have been found then, though undoubtedly the attack of grippe tended to aggravate certain symptoms already present.

Considering the voluminous literature upon diabetes in its many bearings, it must be granted that the *dermatoses diabeticæ* have not been exhaustively dealt with, and comparatively little is to be found concerning them in the text-books. It is for this reason chiefly that I wish to put on record a series of eruptions extending over several years, which have been of much interest to me and may help to draw attention to these conditions, and

aid in the final determination of the affections which are to be included in the class of glycosuric dermatoses. I was first asked to see the following case with a colleague, several years ago:

There was then present upon the chest and side of the neck a herpes closely resembling a zoster, but without marked neuralgic pain. The diabetes had already existed for about two years, and the lesions occupied, according to the patient's statement, the same locations upon which a year before there had been a number of water-blisters caused by rubbing the chest with strong ammonia. The herpetic lesions soon healed under mild treatment. About two years later the family physician having died, the patient came under my own care, and for the past three years has been seen at irregular intervals and has observed the prescribed diet and regimen with irregular persistency. The urine has contained from two to six per cent. of sugar and has had a specific gravity which varies but little from 1032.

Three years ago, when I was asked to prescribe for her, there were present upon the scalp, extensor surfaces of the arms, wrists, backs of hands, thighs, legs, and backs of feet, rounded lesions, which were, according to the patient's statement, irritable rather than itchy. As they had existed for some time, many had changed in appearance by the more or less constant picking and scratching, to which they had been subjected. The eruption, as a whole, much more closely resembled some cases of acne cachecticorum, which I had seen, than it did acne necrotica. These lesions were much more obstinate than those of acne varioliformis, but with a vigorously enforced diet and treatment directed toward the diabetes, including the use of codein, gave way after a time to the local use of ammoniated mercury ointment, which is usually so promptly efficacious in acne varioliformis. Other local antiseptic and reduction agents, such as resorcin, were occasionally employed. Such necrotic lesions, as above indicated, have continued to occur from time to time, until the body is covered with rounded, depressed, atrophic, whitish cicatrices of irregular size. New lesions are prone to develop just at the margin of some of these scars, so that the latter are becoming more and more elongated from the impinging of the new scars upon the old.

In September, 1893, at a time when the percentage of sugar was high as a result of certain liberties at table, the lady was seized with what I can best characterize as acute multiple gangrene of the skin. When I saw the lesions, which were for the most part upon the arms and legs, the epidermic slough had separated in some, while adhering in others as a grayish- or greenish-black, dry eschar, attached in its central part and loose about the edges. The ulcerated surface, which was very superficial, continued to extend at the periphery until some lesions attained the size of a quarter-dollar silver piece, rather oblong or oval, than round. The surface had either a thin diphtheritic-like covering, or was grayish-yellow, some with the red points of the papillæ showing through. The appearance of the lesions was almost identical with that of a case of acute multiple gangrene in an hysterical girl which I treated in 1890. In the latter case, however, the largest lesions reached a diameter of three or four inches, and left dollar-sized keloidal scars.

A strict diet was enforced and moderately large doses of codein were given. Improvement took place rather slowly, the patient keeping her bed for about a fortnight.

The separate lesions were painted with benzoin in collodion, or aristol in collodion after the surface was freely dusted with aristol powder.

At the present time, while the smaller lesions simulating acne necrotica continue to appear at times upon the scalp and elsewhere, there are dark-brown pigment-marks at the site of many of the preceding gangrenous lesions, while surrounding many of the rounded pits, left by the necrotic lesions, is a pigmented areola or halo.

The appearance of the whole body at first glance is, in a slight measure, suggestive of leprosy, and without going carefully into the history, it would not be astonishing if one made a diagnosis of syphilis. There is one peculiarity of these pigmented areas to which I desire especially to call attention, and that is the marked growth of strong, dark hairs, limited abruptly to the patch in which pigment has been deposited. While much more noticeable in the irregular-sized patches corresponding to the preceding dermatitis gangrenosa, the same thing is seen to a lesser degree in the pigmented rings surrounding the cicatrices, due to the necrotic dermatitis, and which are themselves pigment-free. Upon the backs of the wrists and forearms, the contrast between these hair-bearing pigment-areas and the whiteness of the surrounding skin suggests vitiligo. The resemblance is, however, due more to an optical delusion than to reality. And this brings me to speak of bronzing of the skin in diabetics as a condition *per se*, and not secondary to other lesions.

This melanodermia is usually seen in cases of progressive cachexia, which run a comparatively short course. The urine does not seem to differ in general characteristics, or in its sugar-contents, from that of non-pigmented cases, and Dr. Auscher failed in his attempt to discover that it contained pigment. Many of the symptoms are severe, and dyspeptic manifestations with dryness of the tongue and inflammation of the jaws are apt to be much more pronounced than in ordinary cases. Here there is no suggestion of vitiligo, but, on

the contrary, the skin is uniformly darkened, showing however more especially upon the exposed surfaces and about the genitals. Dr. Dutournier[1] likens the color to a leaden hue, or blackish-gray, with a certain metallic luster. The period at which this cutaneous pigmentation appears is ill-defined, coming on, as it does, in a slow and gradual manner. Toward the final stages of the disease, according to Dr. Dutournier, it may either become more marked on the sites of predilection mentioned, or, on the contrary, it disappears to make place for a grayish color resembling that of the skin of uncleanly individuals. Until recently it was held that in the bronzing of diabetics the mucous surfaces escaped, and that pigmentations in the mouth pointed rather to the disease of Addison. Professor Mossé, however, in 1894,[2] demonstrated faint pigmentations upon the inner surfaces of the cheek and lip of a diabetic subject.

Aside from Addison's disease, we have to distinguish diabetic pigmentation from that caused by the prolonged use of silver and arsenic, as well as from that which is consecutive to prolonged cutaneous irritation, such as one sees in inveterate phthiriasis, and from certain atypical instances of icterus.

Erysipelas, which is among the more unusual dermatological complications of diabetes, may be the means of hastening the fatal termination as illustrated by a case brought into my service at the City Hospital, on February 19, 1894.

The patient was a man of forty-four years, who weighed 350 pounds, and had been transferred from one of the hospitals in the city. Presumably because of a history of specific infection, dating back some twenty years, and possibly from the supposed specific nature of the lesions which were present at the time upon the skin surface, he was admitted to the syphilitic ward. Here it was discovered that the urine contained a very high percentage of sugar, being virtually "loaded with sugar," as the history recorded it—a discovery which, so far as we could judge, had not been made before. One month previous to admission the patient went through an attack of erysipelas, to which he attributed his present condition. Ten days before entering the hospital, and some time after the erysipelatous process had ceased to manifest its presence, abscesses began to develop upon the back and arms. These lesions became very painful, and caused extensive destruction of tissue, so that a probe could be passed five inches into the fatty tissues of the back, perpendicularly to the surface. An antidiabetic regimen was ordered and appropriate local dressings were made, but the already advanced sloughing of tissue became daily greater and the patient's condition more alarming, new abscesses forming rapidly on various regions of the cutaneous surface. On or about March 10th the erysipelas recurred, spreading rapidly from one region to another, until the face and head became involved. On March 14th, coma developed, and in this state the patient died on the following day, less than a month from the date of his admission. Such a history teaches us among other things, that syphilis may be followed by glycosuria. Cases have been reported by Dr. E. D. Fisher of this city, in which diabetic symptoms followed syphilis, and disappeared under antisyphilitic treatment.[1]

Dr. Feinberg[2] has made similar observations. Personally, I do not recall a case developing sufficiently near the time of infection to make syphilis a positive etiological factor, though I have seen diabetes insipidus follow in the train of syphilitic manifestations, and have now such a case under observation. While gangrenous and sloughing tissues may, by absorption from the products of disintegration, give rise to glycosuria and multiple abscess, I doubt whether this was the case in the instance just described, not only from the rapidly fatal ending, but because we know how prone diabetes is to attack such extremely obese subjects.

Nail-affections occur with comparative frequency in diabetes, just as they do in syphilis and leprosy. Paronychias are quite common in their acute suppurative form. Small pus-collections develop along the lateral margins or in the nail-fold, and extend beneath the nail-body, unless they are opened and treated early. These may occur in any stage, but often indicate a high percentage of sugar, especially when one finger after another becomes affected. Spontaneous hemorrhage may take place beneath the nail, perhaps raising it from its bed and ultimately resulting in its being cast off.

Following suppurative inflammation in the nail-region, papillomatous growths of a wart-like nature may occur. Kaposi speaks of warty protuberances following ulcerative lesions of the skin. The term *papillomatosis diabetica* which he employs is, I think, a good one, directing attention, as it does, to this tendency in some cases.

Zoster was thought by Vergely[3] to be frequently caused by diabetes. Aside from the case I have briefly referred to, I have no personal experience to offer, but in this connection Hardaway's case of zoster-like xanthoma, in which sugar was present, is interesting.

Pruritus, and especially pruritus vulvæ, has claimed more attention than any other skin-affection connected with diabetes, because of its almost constant occurrence at some stage of the disease, and particularly because of its severity and the slight effect of usual antipruritics, unless the cause is discovered and the disease itself is attacked with vigorous remedies.

Undoubtedly the fungus (*Saccharomyces cerevisiæ*) deposited from the voided urine about the prepuce in the male and the labia in the female, produces by a local irritant action not only a pruritus of these parts, but dermatitis and eczema, which may lead to gangrene. Hence cleanliness and bathing after each urination are advisable. Once a raw surface is established, it would seem that we need no longer invoke the local deposit of sugar from the urine to account for persistent itchiness, since it has been shown by Vergely that in 190 cubic centimeters of fluid collected from the surface of an ulcer, situated upon an edematous limb, 2.25 grams of sugar were present.

In treating these cases it is found that a lotion which acts in a satisfactory manner in one case fails in another. I have seen diluted listerin stop the distressing pruritus after carbolic and menthol solutions and various ointments had produced little effect. Solutions of peroxid of hydrogen, permanganate of potash, hyposulphite of soda, etc., act well in certain cases. In others the physician must himself apply solutions of nitrate of silver or strong solutions of permanganate. The itching may extend into the vagina, in which case the hyposulphate solution (℥ss to Oj) or permanganate (gr. xv to Oj) may be injected. Lotio nigra does well in some instances, while in others distilled extract of hamamelis is all that is required. What I have said in speaking of boils and multiple abscesses I can repeat for pruritus pudendi. Let it always lead you to examine for sugar quite as much as would a high specific gravity of the urine. Eczema and psoriasis occurring in diabetics are usually only incidental, still I am convinced that certain eczemas develop solely because of the glycemia. An acutely developing moist eczema of the lower extremities in stout individuals has led me more than once to suspect glycosuria, which was confirmed on testing. While pruritus, as I have said, is the most likely of all cutaneous complications to occur, xanthoma diabeticorum is the dermatosis most intimately associated in our minds with the disease, although up to 1893 but thirteen cases had been put on record, which have since been increased to thirty. Some observers maintain that the condition is not a xanthoma at all, and the term lichen diabeticus has been applied to it. It surely does not seem to bear a very close clinical relationship to the xanthoma usually seen about the eyelids, occurring as the former does, acutely over a large extent of surface and, perhaps, disappearing spontaneously after a brief period which the latter is never known to do. The lesions are papular or tubercular, less yellow, firmer, inflammatory, and occasion subjective symptoms. That it resembles but slightly xanthoma planum is shown by the fact that Dr. Robinson's case, which so far as I can remember was the only one observed in this country up to that time (1889), was originally presented at the New York Dermatological Society as a case of fibroma cutis.

A most interesting and instructive case, in this connection, is that depicted and described in the "Pictorial Atlas of Skin Diseases," now being published from the models in the St. Louis Hospital of Paris. The case belonged to Dr. Darier, and showed abundant lesions of xanthoma planum and tuberosum in a glycosuric, ictric, and obese subject.

Here, alongside of such lesions as all are familiar with in ordinary xanthoma, there occurred papular and tubercular lesions, corresponding in clinical features to those of so-called xanthoma diabeticum.

In our present lack of knowledge not only concerning the pathogeny of diabetes, but likewise in regard to the connection between hepatic diseases and the occurrence of xanthoma, the present instance which is unique, so far as I know, of a combination of all the features going to make up two hitherto distinct, but in many regards similar, conditions, is, it seems to me, of the greatest interest and importance.

Besides the dermatoses above mentioned, we find, occasionally, in diabetes, malum perforans pedis, deep or perforating ulceration of the plantar surface of the ball of the foot or toe, chronic urticaria, pityriasis rubra (case reported by Horden, *Lancet*, vol. ii, p. 1056, 1893), and others.

The skin in diabetes is habitually dry. I have one patient who complains very much of burning of the footsoles. The skin, too, would seem to be peculiarly vulnerable, healing badly after injury, showing a tendency to sloughing and eschar-formation. It is also apparently in a more or less constant state of receptivity for pus-producing organisms, all of which may be explained by the presence of sugar in the tissues which is possibly excreted by the cutaneous glands. A feature of excoriated or superficially ulcerated lesions is that

they become quickly glazed over or covered with a coating within a remarkably short time, and still show but little tendency to spontaneous healing.

Another noticeable peculiarity is the central necrosis or central gangrene common to many lesions, and, as shown in one of the cases I have reported, there is a tendency to persistent recurrence of lesions at the margin of the scars left by former ones.

While I have not attempted to treat the subject exhaustively, I think enough has been said to indicate my belief that glycosuria, as a symptom of a variety of conditions originating in different parts of the body and still far from being understood, may be attended with a great variety of cutaneous manifestations; that while these dermatoses are at times almost sufficient of themselves to lead to the diagnosis of the presence of sugar in the urine, we know as yet of but few which are sufficiently pathognomonic or peculiar to the disease diabetes to warrant our making of them a class to be called diabetids; that if such a class is to be established, the diabetic pigmentation, the dermatitis gangrenosa, and dermatitis necrotica diabeticorum, of which I have related instances, should find a place in it alongside of xanthoma diabeticorum.

LATENT MASTOID DISEASE.[1]

By EDWARD FRIDENBERG, M.D.,
of New York.

In the great majority of cases the diagnosis of mastoid disease is made without much difficulty; pain, tenderness on pressure, redness and swelling of the integuments, fever and prolapse of the posterior-superior wall of the auditory canal are the leading symptoms in acute cases, while persistence of fistulous tracts, or recurrent edema, characterize those of a more chronic nature. Yet there are not a few instances in which extensive mastoid disease is overlooked, or not even suspected, owing to the entire absence of symptoms, either local or constitutional.

To illustrate some of the forms of what may be properly termed "latent mastoid disease," I shall briefly narrate a few typical cases of the large number I have seen and treated:

Case I.—K. C., a girl of nineteen, was admitted to the German Hospital on August 30, 1891. A year previously, after a severe cold in the head, she had pain in the left ear, followed by discharge, at first bloody and serous; later, purulent. Pain soon disappeared. The discharge persisted for a time, and then ceased. Since then there has been occasional discharge, at no time very profuse, at no time foul-smelling. Hearing, however, has diminished considerably, and later a feeling of pressure was noticed in the ear, for which symptoms the patient sought relief. Patient was a healthy, well-nourished girl; family history and antecedents good. The right ear was normal. In the left ear the hearing was: Ordinary voice, 1 meter; whispering voice, 2 meters; watch, .03 of a meter; Rinné negative; bone-conduction to the left. Inspection showed auditory canal blocked by large polypus; mastoid region normal in all respects. Examination of heart, urine, and lungs was negative.

After thorough cocainization of the polypus, it was removed by the snare. Hemorrhage was free, but was easily controlled. Warm antiseptic irrigations were ordered three times a day. On the following day, violent inflammation of the mastoid had set in, with much swelling and redness of the integuments, and a temperature of 102½°. An ice-bag having been used for about forty-eight hours, without any improvement in the patient's condition, operation was determined upon. On September 2d the mastoid was opened. The periosteum was found slightly thickened and much inflamed; the lateral wall of the mastoid, a mere shell—at most 2 millimeters in thickness; the cells entirely broken down, forming a large cavity with carious walls, filled with pus and granulation-tissue, communicating freely with the antrum and middle ear.

Here was a case in which carious destruction had been going on within the mastoid, probably since the attack of acute middle-ear suppuration one year ago—certainly for several months. At no time had there been symptoms pointing to implication of the cells, and two days before the operation a careful examination had failed to detect anything abnormal about the process. The patient recovered promptly.

Case II.—E. J., man, forty years of age, was referred to me for a persistent suppuration of the right middle ear, which had resisted routine treatment at the hands of his family physician for five weeks. At the onset of the acute middle-ear suppuration there had been slight pain and tenderness over the mastoid, but not more than is usually found in acute otitis media suppurativa. These symptoms disappeared under the use of hot poultices and syringing with hot boric-acid solution. The examination revealed nothing of importance, excepting an unusually profuse, non-odorous, purulent discharge, the pus being of a light yellow hue, and perhaps a little thinner than is usual. For six weeks the most varied treatment was resorted to: Constant syringing with warm aseptic saline solutions; peroxid of hydrogen, astringent and antiseptic instillations; washing out through the Eustachian tube. All failed

[1] Read at the twelfth annual meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn on May 26, 1896.

to reduce the amount or alter the character of the discharge. In spite of the absence of the usual symptoms relied upon for the diagnosis of mastoid trouble, I came to the conclusion that such an amount of pus could not be secreted by so small a cavity as the cavum tympani and that we had to deal with an empyema of the mastoid process. With some difficulty the patient was induced to submit to an operation, which revealed a condition very similar to, but even more pronounced than, the one noted in our first case, viz.: Extremely thin-walled mastoid; an enormous cavity, which had already destroyed the median wall of the process, for, upon attempting to remove the last vestiges of granulation-tissue with a sharp spoon, a sudden, extremely profuse flow of dark venous blood alarmed the operator and almost jeopardized the life of the patient. In an instant many ounces of blood were lost. As soon as the danger was realized, the index finger was pressed upon the lacerated lateral sinus and the bleeding at once stopped. The assistants tied the arteries, put in sutures above and below, and completed the toilet of the wound. A compress of iodoform gauze was quickly substituted for the finger, the cavity stuffed with sublimate gauze, and pressure-bandage applied. For a week the wound was dressed without disturbing the iodoform-gauze pledget over the tear in the sinus. On its final removal, the sinus was found healed and its wall covered with healthy granulations. Convalescence was slow, but uneventful.

In this case also the acute caries of the mastoid cells must have been coincident with the first signs of middle-ear trouble; and had operative interference been still further postponed, sinus-phlebitis and pyemia would have surely resulted, perhaps with a fatal termination.

Case III.—A. L., man, age twenty, was admitted on July 2, 1888, to the German Hospital, for recurrent febrile attacks, with slight chills. The attacks occurred at irregular intervals of from two to five days, reaching 104½° in a few hours, being followed by rapid defervescence and some perspiration. In the intervals the patient was afebrile and in fairly good condition. The spleen was slightly enlarged, and the patient was treated for malaria without marked improvement. As his right ear had discharged since childhood, I was requested to examine the case. I was unable to discover anything but a chronic suppurative otitis media, with inspissated, fetid pus, after the removal of which the membrane and all the ossicles were found to be absent. The mastoid was apparently healthy, but I suspected septicemia from retention of decomposing discharges, and ordered the usual treatment.

While considering the advisability of opening the mastoid for the purpose of thorough drainage, sudden, acute, painful swelling over this bone made the diagnosis more clear and led to immediate operation. We found subperiosteal abscess, communicating by a small perforation near the tip, with a very large, smooth-walled cavity in the mastoid, filled with cholesteatomatous masses and cheesy pus, on the removal of which the hole in the bone easily contained ten grams of fluid. There was free communication with the antrum, and thorough disinfection of all the parts was easily secured. The walls of the cavity were scraped, and the wound healed gradually, with a deep, indrawn scar. Symptoms of septicemia, however, persisted for some time. The right shoulder-joint became swollen and painful. Lobular pneumonia of thrombotic or pyemic origin developed. It was four months before the patient could be discharged cured.

Case IV.—F. W., girl of eighteen, seen by me in consultation for severe vertigo and nausea, which had come on suddenly and had lasted about three days when I was called. I had known this young woman eight years, had prescribed glasses for her and examined her ears once or twice during this time. When five years of age she passed through a severe attack of scarlet fever, with otitis media, the purulent inflammation sweeping away the drumhead and all the ossicles on both sides. When I first examined her, I found her extremely deaf, the wall of the tympanum being almost completely covered with epidermis, and merely moistened by a minute amount of pus, which was not fetid. The patient wore artificial drumheads, which materially increased her hearing power, and had always been a subject of interest to me, as I had found very few patients benefited by these contrivances. During all these eight years there had been no aural symptoms. The vertigo was very marked whenever the patient attempted to rise or moved her head quickly, the patient falling toward left side. It was followed by slight nausea, which became more marked if the motion continued. The family physician had excluded the possibility of any etiological factor but an affection of the brain or ear. Both ears showed absence of drumhead and ossicles, and dry, bony walls of the cavum tympani, but the mastoid appeared to be normal.

An examination of the eye was made, with negative result. The case was treated expectantly for two days, when slight pain was experienced and tenderness upon pressure observed in the neck just below the left mastoid process. On consultation, we determined to open the left mastoid. This being done at the customary site, the bone was found very hard and sclerosed. At a depth of 12 millimeters a cholesteatoma was found in a cavity about the size of a lead-pencil and about 6 millimeters deep, running inward toward the semicircular canals.

The patient made a good recovery, all symptoms abating materially at once. Slight vertigo, however, persisted on rapid movement for about two months. The bony cavity and the artificial hole in the mastoid became closed throughout by bone.

In this case it would be difficult to fix the time

at which the mastoid disease commenced, but I believe we are safe in presuming that it had lasted several years.

As above stated, these cases are merely types, and I have observed quite a number resembling one or the other more or less closely. In all these cases, disease of the mastoid, acute or chronic, produces a great destruction within the bone, symptoms not arising until the pathological process approaches or reaches the meninges or the semicircular canals on the one hand, or the periosteum on the other. And the lesson which they teach is: That in any case in which purulent discharge from the middle ear continues, or extensive carious destruction of the contents and walls of the tympanic cavity exists or has existed at any time, latent mastoid disease should be considered as a possibility and guarded against.

DISCUSSION.

Dr. J. E. Sheppard: Some symptom has always existed in those cases that I have seen sufficient for a probable diagnosis of mastoiditis. Among the cases I remember are two or three —several, perhaps—where the only possible indication for operation was a profuse purulent discharge, continued over too great a length of time for a simple acute middle-ear suppuration. I have repeatedly opened the mastoid and found pus in larger or smaller quantities when there was not any discharge from the tympanic cavity. In other cases the only symptom present indicating trouble was pain, which was not located in the mastoid at all, but over some other portion of the affected half of the head. At other times there has been no pain present, but slight tenderness over the mastoid—so slight it could only be elicited by very firm pressure or percussion.

The history of one of my cases emphasizes the importance of one of the symptoms of which Dr. Fridenberg spoke, and that is the drooping of the posterior-superior canal-wall.

The patient was a man thirty-five years old. Two years before he had a simple recurrent middle-ear suppuration, which rapidly recovered. At the last attack, he came with what was apparently a similar recurrent middle-ear suppuration. He had considerable pain in the mastoid region, with tenderness, which, with the usual abortive measures, subsided. He had no discharge from the ear after about two weeks of treatment, no pain, no tenderness over the mastoid; the only symptom left was the drooping of the posterior-superior wall of the canal, which seemed no more than usually sensitive. The man returned to his work, and I was about ready to discharge him as cured. I told him, however, as a precautionary measure, to come back for a final visit in a few days. About two days after this he came to me in great haste, saying that he had been seized during the preceding night with severe pain, fever, and vomiting. I operated the same day. I found a little granulation-tissue and pus in the mastoid antrum; practically no pus in the tympanic cavity, but a carious canal leading from the upper portion of the tympanic cavity, the so-called attic into the brain cavity. Undoubtedly he had had a suppurative process going on in the mastoid antrum and tympanic attic all the time, even though his symptoms had subsided so entirely. This process had extended through the roof of the tympanum and set up a meningitis, which caused the man's death, simply because I had not learned to realize the importance of this one symptom. I had never seen in the books nor heard the statement made that drooping of the posterior-superior canal-wall, when attended by absolutely no other symptoms, was a sufficient indication for operation.

Dr. Mathewson said that it is somewhat difficult to get comparative statements as to the number of cases relieved by operations on the mastoid, as compared with those which were not treated by operative procedure—at least not by removal or chiseling away of the bone.

He has sometimes thought, too, that the mastoid got blamed for deaths that it was not quite responsible for, because in a number of cases of *post-mortem* examinations he has seen, the mastoid was not found to be the cause of the trouble. The brain-abscess or meningitis had not originated in the mastoid, and there was no mastoiditis to account for the death.

Dr. Alderton of Brooklyn said that any bulging of the posterior bony wall of the canal, even so far out as the bony orifice, in connection with tenderness and other symptoms involving the mastoid, was a pronounced indication for operation, and cited a case in which the bulging had been confined to the inferior-posterior wall, just at the orifice of the bony canal.

Dr. Fridenberg: The gentlemen who have been kind enough to discuss my paper are all evidently in agreement with me on the essential points which I brought forward. Knowing that I was to address a meeting composed principally of general practitioners, I had tried to emphasize this point: That, as a rule, when we operate for mastoid disease, I should say, perhaps, in ten per cent. of the cases, it has lasted a long time with-

out our knowing it, and in ninety per cent. it has been there, but not reached the point where operation was necessary. But almost every aural surgeon is surprised each time he operates at the great amount of destruction he finds already present.

FUNCTIONAL INDIGESTION, ITS CAUSES AND TREATMENT.[1]

By J. M. G. CARTER, M.D., Sc.D., Ph.D.,
OF WAUKEGAN, ILL.;
PROFESSOR OF PREVENTIVE AND CLINICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE, ETC.

The term indigestion refers to a condition, not a disease; this disturbance, then, is always functional. The use of the word "functional" in the title of this paper is to direct attention to those indigestions which are in no way connected with any organic lesion of the stomach. Hence the cases which occur in cancer, acute and chronic gastritis, ulcer, and other lesions are eliminated from our discussion; likewise dyspepsia with its exacerbations, which accompanies atrophy of the stomach and cicatrices following ulcer, does not come within the limits of this paper. Cases of indigestion due to diseases in other parts of the body are classified here, as are also those caused by mental or emotional impressions. An indigestion arising from a neurosis is functional in the sense here assigned to that term. To understand these views, it is necessary further to differentiate indigestion from dyspepsia. We use the term indigestion to indicate a brief, single attack of derangement of digestion, while dyspepsia refers to a pathological, perhaps chronic, condition, which encourages or allows a number of attacks of slight or severe gastric or intestinal digestive disturbance, occurring in succession, and often covering considerable time.

Thus limiting our discussion, it may be observed that this form of indigestion is caused by (1) some indiscretion in diet; (2) some irregularity in the time or manner of taking food or drink; (3) some bacterial effect upon the food; (4) some neurosis or reflex disturbance, or (5) some sudden mental or emotional impression.

1. Indiscretions in diet include failures in preparing food properly, as well as the selection of proper quality and quantity. Idiosyncrasies prevail, which, if disregarded, frequently precipitate an attack of indigestion. In cases of anemia and exhausting diseases, the reduced power of the stomach may allow an indigestion to occur after taking food which, under normal circumstances, agrees perfectly. At such times, the secretion of gastric juice is diminished on account of the altered condition of the blood; the peptic glands do not receive the stimulus which normal blood gives them, and the supply of blood is reduced so low that with normal activity they still would be unable to secrete a normal gastric juice. If under such circumstances a full meal is taken, or a diet chosen which requires greater digestive power than the stomach possesses, indigestion is the result. Attacks of indigestion are precipitated in cases of dyspepsia when the patient has been thinking so steadily that the stomach is deprived of a full supply of blood, especially do these occur if the individual returns at once to his work, not allowing time for digestion to be well started before the brain withdraws the gastric blood-supply. The headaches resulting at such times do not indicate brain-exhaustion, but stomach-exhaustion. The gastric secretion is diminished, just as in anemic cases. The "nervous" or "bilious" headaches of business men frequently are indications of indigestion of this variety, and illustrate one very prominent class of cases of functional dyspepsia. A predigested or mixed diet on days when patients need to work hard, will often remove the tendency to these attacks.

2. Physicians and others who cannot or do not have meals at regular hours, frequently suffer with indigestion caused by such irregularity. The derangements due to rapid eating are well known. The checking of gastric secretion by drinking cold or iced water is detrimental in cases of diminished secretion or impaired tonicity, except when taken at such an hour as will cause the reaction to appear when food is taken. In cases of hypersecretion of gastric juice, cold drinks with meals do little if any harm, provided the food consists mainly of proteids; but if the food consists mainly of starches or sugars, drinks with meals are objectionable. Idiosyncrasies prevail here, however, as in other cases, and sometimes the dilution of the gastric contents, by large draughts of liquid, interferes with digestion of the proteids likewise, at least delaying the process, whether the drink be cold or hot.

3. A very prominent cause of indigestion is the presence in the stomach or bowels of bacteria or their products. Sarcinæ, the *Bacillus lacticus*, *B. butyricus*, and other bacteria, readily inaugurate fermentative processes in the stomach under circumstances of diminished tonicity or indiscretions in diet. The gases and other products of these agents may cause pain and other disturbances in the intestines with diarrhea, etc.

[1] Read before the Illinois State Medical Society, May, 1896.

4. In the course of ataxia and other nervous diseases, the occasional effect upon the vasomotor system is such as to interfere with gastric secretion and precipitate an indigestion. This encourages the development of bacterial operations and products. Gastrodynia, gastralgia, or neuralgia of the stomach, may interfere with digestion, and induce conditions which may develop favorable culture-media for bacteria, and precipitate an attack of indigestion. The severe pains of renal colic, or an attack of gall-stones, may cause similar functional disturbances with deranged digestion.

5. Finally, a very common cause of indigestion in stomachs where no organic lesion exists, where the food is proper, and mastication well performed, is the sudden impression made upon the nervous system by some profound disturbance to the emotions. Fear, anger, grief, surprise, intense or anxious thought, may interfere with digestion. The temporary shock to the vasomotor system which causes constriction of the arterioles of the stomach, impedes secretion of the fluids necessary for the process of digestion, and here again the growth of bacteria is encouraged.

The following indications may be regarded as pointing out the course of correct treatment in these cases, to be varied to meet the necessities of individual patients: (1) Remove the cause; (2) check or prevent the growth of bacteria; (3) assist digestion; (4) repair damages done.

1. If improper food is the cause, it should be immediately corrected ; if food remains in the stomach it should be immediately removed by emesis or lavage. Nothing can be done in many cases until the stomach is empty. If some disturbance of the vasomotor system is the cause of the indigestion, the administration of nervines to quiet the general nervous symptoms, and nitro glycerin to dilate the capillaries, and allow the blood to flow freely to the stomach and increase the secretion of gastric juice, will yield excellent results. The reasonableness of this treatment is readily seen. Nervous shock—a fright, sudden anger, grief—by its stimulation of the vaso-constrictors or paralyzing effect upon the vaso-dilators, prevents the flow of blood about the peptic glands in sufficient quantity to permit a normal production of hydrochloric acid. A deficiency of hydrochloric acid in the gastric juice, even when temporary, causes at least three abnormal effects: (*a*) A failure to digest proteids; (*b*) it permits putrefactive changes in the food; (*c*) by failing to excite peristalsis it allows the food to remain too long in the stomach. The occurrence of these facts make a fourth undeniable in most, if not in all, cases, *viz.*: The formation of a favorable culture-medium for bacteria.

If the nervous impression is not too great, and there is only a reduction of the normal amount of hydrochloric acid—not a complete checking—the administration of pepsin and hydrochloric acid may be sufficient to overcome the paroxysm. They assist in the digestion of excess of food, and in case of the presence of organisms they serve another purpose. They help to restore the gastric juice to its normal condition, and then enable the stomach to repel the invaders.

2. The indication is to prevent or check the development of bacteria. The rational course to pursue, and one which should be borne in mind from the beginning, is to aid the natural forces, as already pointed out, by trying to restore the normal secretions. Very frequently the urgency of these cases is so great, however, that more rapid and positive methods must be adopted. If the stomach has been emptied, and frequently when it has not, the use of antiseptics, like carbolic acid, salicylate of bismuth, or salol, will give quick and grateful relief. Cases of gastrodynia may frequently be relieved in this manner. I am now treating a patient with nephrolithiasis who has occasional attacks of gastrodynia, due apparently, to an accumulation or formation of gas in the stomach, caused by indigestion. The most successful treatment of this case has been three-grain doses of salol, from four to eight times a day. When the abdomen is tense and the pain in the stomach severe, three or four doses of the salol relieve the patient entirely, leaving the abdomen soft and normal. In similar cases of gaseous distention accompanying or following indigestion in children, I have used salicylate of bismuth with marked success. I have used carbolic acid in hundreds of cases for gaseous distention with very gratifying results. Resorcin is milder, and does well in many cases. Gelsemium may be given with any of the antiseptics above mentioned for its soothing effect upon the gastric mucous membrane, and for its anodyne influence upon the nerve-terminations in that membrane.

A very important part of the treatment of these cases is required to overcome the results of the presence of bacteria and their products. The pain in the stomach or bowels caused by the irritating gases, remains of undigested food, etc., may require anodynes; and the headache, caused by the absorption into the blood of bacterial alkaloids, may require the bromids and other nerve-

sedatives until the blood can be changed or the poisons eliminated. Diarrhea is a very common result, but one which can usually be controlled by antiseptics; if particles of undigested material remain in the intestine, they should be removed by a cathartic. To produce catharsis and at the same time act as an antiseptic, calomel is pre-eminent, and may be given in doses of one-tenth of a grain with bicarbonate of soda, one grain, every hour or two for adults, and every two or three hours for children. Half of this dose acts well for infants under one year. For simple antisepsis, salol, salicylate of bismuth, boric acid, carbolic acid, and resorcin frequently do good service. Salicylate of bismuth, salol, and resorcin, in one- or two-grain doses every two or three hours for children, will often give most satisfactory results; smaller doses should be given to infants, and larger to adults.

3. The digestion requires assistance very often on account of some weakened condition of the system, as in convalescence from acute diseases, or because of an excess of food. It is necessary to recall the digestive ferments, and their specific action at such a time in order that assistance may be intelligently rendered. The administration of diastase and pancreatin, when non-nitrogenous foods are imperfectly digested, is sometimes followed by excellent results. Hydrochloric acid and pepsin often act quickly and hasten the digestion of nitrogenous foods. When the digestion of both classes of food is at fault, peptenzyme not infrequently gives relief. Ipecac in six- or eight-grain doses, three times a day, increases the biliary secretion.

4. The fourth indication seldom requires attention except in these debilitated cases, and where the offending materials have remained in the alimentary canal an unusual time. In the former case, tonic and corrective treatment may be required. Lactopeptin and phosphates will be found especially serviceable. Malt often is useful. The elixir of pepsin with aromatic sulphuric acid assists digestion, stimulates the secretions of the stomach, the liver, the pancreas, and probably the intestines. When the undigested materials have remained unusually long in the bowels, antiseptics will be required in addition.

It will have been observed that the writer emphasizes the importance of antiseptics in the treatment of functional indigestion, as he has elsewhere done in the treatment of dyspepsia. It is more essential in dyspepsia, but it is important in indigestion.

THE BUSINESS END OF IT.[1]

By GEORGE W. MILES, A.M., M.D.,
of Oneida, N. Y.

The presentation of formal papers at stated meetings of the members of our profession, thereby affording opportunity for discussion and comparison of notes, is conceded to be a custom furnishing to us all both pleasure and profit. I have thought best, however, to speak of a matter which I feel sure is of more than passing interest to all of us and of decidedly practical importance.

While the profession of medicine is an ancient and honorable one; while its study and practise are of entertaining and engrossing interest; while there is no nobler field for earnest study and excellent effort; while it furnishes unlimited opportunity for kindly words and charitable deeds; while it is the one occupation of all others to call out the best of our moral natures as we administer to human suffering; while we may and should take pride in our calling, and as we pursue our busy way delight to do good to all men; while we love to believe that our life-work is placed on a plane even beside that of those who preach the Gospel of Christ; and while it may almost seem a sacrilege to ask you, even briefly, to withdraw your minds from considerations so high, so noble, so beneficent, still I feel it is the truth to say that so far as most of us are concerned, at least, we must support ourselves and our families by our labors, and the question therefore becomes an important and a practical one, "How much is there in it?" I hope I may not be thought mercenary, then, if I give some consideration to-day to the matter of the kind of pecuniary harvest one may gather after a lifetime of toil in the medical profession.

The statement admits of no questioning, I think, that doctors, as a class, are far from being rich men. In proportion to the capital invested in money expended for education, in culture, in hard work, in skill, in experience, there is no class or business, considered as a business, so poorly paid as ours. A recent writer says: "Physicians are generally admitted to be poor financiers. There is probably no class of men who realize so little financially from their labors. Persons are often astonished to learn in how straitened circumstances many physicians, who were known to have had large practises, leave their families at death. They live moderately, indulge in no luxuries, yet after all debts are paid there is left to the family, probably, only a very humble home, and that with a mortgage upon it."

[1] Read at the meeting of the Third District Branch of the New York State Medical Association, held at Auburn, N. Y., June 11, 1896.

This is a picture which is not overdrawn. The large accumulations of wealth resulting from transactions in the commercial world, are unknown in the medical profession. Occasionally a physician has met with goodly returns from wise investments, and the beginnings for such investments may have been earned in the profession, but riches attained solely in and by the practise of medicine I do not believe to be possible in these days, outside of a few of the specialties in the larger cities. One of the large New York dailies has recently published a comprehensive list of the millionaires of this country, and in that list is not to be found the name of one practising physician.

Even a comparison of fees with those of other professions is not advantageous to our own. In the village of my home, not long since, a practising attorney collected a bill for a client of $500, and for that service charged and received a fee of $125. But a physician in the same neighborhood, having rendered some service far above and beyond any valuation, perchance where human life itself hung in the balance, is told, when he presents his bill of $1 per visit, that it is too much, and that the physician who preceded him in attendance upon the family never charged more than 75 cents. This is another picture which is not overdrawn, either; in fact, it has even actually happened in the experience of the writer. With such a remarkable inconsistency in the matter of fees between the professions of law and medicine, it becomes at once apparent that there is something wrong somewhere—something needful to be remedied.

There are probably more factors than one entering into the condition which render the profession of medicine a poorly paid one. There is the fact of the extremely crowded ranks of the profession; also the fact that we are all probably very virtuously trying to live up to the teachings of the medical code of ethics, and although its principles are lofty and honorable, it certainly deals a rather severe blow to all aspirations for money-getting. Then there is the large amount of charity work which we must all do—the care of the sick and suffering among the Lord's poor (and it should fill us with gratitude when we stop to think that there are those even poorer than the doctors). Such charity services we should not and do not shrink from. It may not be the fault of the poor that they are poor, nor is it ours that we must serve them. There is the other class, though, the Devil's poor, or "dead beats;" and the fact that so much of our precious time is given up to them for nothing is, I believe, decidedly our own fault. It will be well with us all when with this class of patients we shall invariably adopt the custom of declining with thanks their entire business.

Again, there are the necessarily enormous expenses of professional life. Also, there is the competition of the public hospital and the private hospital, thoroughly advertised (within the code, of course), and the free dispensaries. Once again, there is the common practise which exists among all men, and women too, of passing around among their relatives, friends, and neighbors the prescription which some poor doctor has received only one very modest fee for. But this brings us to another subject, one worthy of an essay all by itself—to dispense or not to dispense; whether 'tis better to bear the ills we already have and go on writing prescriptions, by means of which the doctor shall grow poorer and the druggist richer every year, or to write not at all. Upon this special discussion I do not desire at this time to enter.

Some of these matters which help to make the average medical income weigh lightly in the financial balance, we may not be able to remedy. There is, however, one thing which physicians can do and which, as a matter of fact, I think they sadly neglect. I refer to the application of prompt business methods in the collection of their accounts. The nearer the doctor's bill is brought to a cash-transaction and -basis, the better, not only for the doctor, but the debtor as well. An absolute cash-basis for doctors' bills may partake too much of the millennium to be practicable in everyday life, but it is certainly true that we need not allow the pendulum to swing to the other extreme and permit the physician's account to become the most distinctive credit-system in all the world; and that I believe it is to-day.

Something may be done by physicians, individually and collectively, in the protection of their financial interests. Doctors are proverbially poor collectors. They are pressed for time, it is true, but nothing is or can be of more importance to them than their bookkeeping, and it should be carefully and methodically done, instead of delaying it until odd times and thereby embarrassing many individuals who would pay, but whose lives are too short, or their residence in any given place not sufficiently extended, to meet the requirements of the slow bookkeeping which many physicians indulge in.

Doctors' bills are not presented with sufficient frequency. There seems to be an idea prevalent in my own immediate neighborhood, and I pre-

sume elsewhere, that it is not genteel to present a doctor's bill in less than a year from the time it is made. Why such an idea should exist, while the butcher and grocer and every other tradesman is steadily presenting the doctor his account in from thirty to sixty days, I do not know. I do know that I have lost many a dollar by neglecting to present my account when it was fresh in the mind of the patient. It is probably true of all bills, medical as well as others, that they had best be collected early and often. They are then smaller and more easily paid. I know of no reason why physicians' accounts should not be presented and collected at the end of every ninety days.

If a uniform method could be adopted by all the physicians of any given neighborhood, and surely there is no reason why there may not be, it would be more helpful to all. In every community, large or small, there ought to be sufficient harmony among medical men that concerted action might be taken as to an established fee-bill to be religiously and absolutely followed by all, so that a uniform method in the collection of accounts might be established, so that lists of delinquent debtors could be exchanged, and nothing be omitted which should tend to the upbuilding of each physician's business and material interests. It would not prove amiss should we draw a lesson from the trades-unions and organizations for mutual protection which are so familiar to us in the business world.

If the medical profession is to be placed upon a higher plane in the matter of its emoluments and rewards, so that as old age comes on and the hard work of youth and middle life is no longer possible, we shall be assured of competencies and positions of security, then indeed we must think once in a while of business, and not always of science. The sharp competitive struggle should not lead us, in our anxiety to be seen doing business, to do it for less fees. Fees are already too low, and should be raised, rather than lowered. Neither should it lead us to do for those who do not pay us and do not mean to, and at the same time are of the class who have money for everything else in the way of luxuries and pleasures. It should ever be our policy, early and late, in season and out of season, to teach the laity the lesson which is of so great importance to us, that we as laborers are worthy of our hire. We shall get little outside aid; even the laws of our land do not help us much. One lonesome legislator, indeed, during the last session in this State, introduced a measure to make doctors' bills against estates a part of funeral expenses to be settled as preferred accounts, but he received little sympathy from his brother statesmen. However the medical legislation of the present time along the line of higher standards of medical education may assist future generations of medical men by the exclusion of quackery, it is of little help to those of us now in the field. We must help ourselves.

We are not necessarily humanitarians and philanthropists to the exclusion of every other sentiment; there is a higher duty—that of self-protection. It is too narrow a view to take to be contented simply with a good living as we go along. Ample provision for the future is a duty which we owe to ourselves, to each other, to our families, to our children who will live after us; and deep in our innermost hearts should be the resolve to advance by all the means in our power the business status of our profession.

CLINICAL LECTURE.

THE ASPIRATION AND CHEMICAL EXAMINATION OF THE GASTRIC CONTENTS [1]

By A. L. BENEDICT, A.M., M.D.,
OF BUFFALO.
LECTURER ON DISEASES OF THE DIGESTIVE ORGANS, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO.

We shall consider this morning the chemically diagnostic use of the stomach-tube, removing samples of chyme, and investigating the course of digestion by analysis.

To be strictly scientific, I should like to treat every case of gastric disease only after chemical examination of the chyme —not neglecting other methods. As a matter of fact, I do not practise this in more than half of the cases that present themselves. The average patient prefers guesswork, and a possible delay of relief, to the scientific but disagreeable procedure of passing the tube. The test is best applied after a light and simple meal. I like for most cases the following meal which represents all kinds of simple and nutritious foods, including fats, carbohydrates, and both animal and vegetable albumins, which are digested in a slightly different manner. It consists of a slice of bread and butter, a chop or small steak, broiled, and a glass of water.

The patient, Dr. ——, is a comparatively young man, ordinarily in good health, who complains of distress after eating, of sick headache, of some belching of gas, of lack of appetite. The bowels are usually regular, and there is no history of vomiting. The case appears to be a transient dyspepsia, since there is no dilatation of the stomach, and since other organic conditions have been more or less positively excluded. It is also probable that the dyspepsia is of the common subacid and atonic type. In men, regularity of the bowels is the usual condition with dyspepsia. The bowels may be irritated into a diarrhea by the unexpected discharge into

[1] Delivered before the senior medical students of the University of Buffalo.

the duodenum of a mass of fermenting chyme, but when the stomach-trouble begins gradually and persists, the intestine usually accommodates itself to circumstances. In fact, there are many persons who consider themselves in good health who have a chronic failure of the gastric function, the bowels performing vicariously the duties of the stomach. Vomiting, it seems to me, should not usually be considered an abnormality, and very seldom an abnormal symptom of the stomach. It is a conservative process, allowing the stomach to rid itself of poisonous or irritating materials, or of food which is irritating simply because it is superfluous. The horse, which rarely vomits, is especially subject to violent and dangerous functional gastro-intestinal disturbances. The cat, which vomits readily and voluntarily, almost never has such trouble. As a matter of experiencc, I am rarely consulted by persons who vomit freely. Vomiting, however, becomes serious when it is a reflex from cerebral, intestinal, peritoneal, and uterine troubles, and when it marks severe organic lesions of the stomach.

The passage of the stomach-tube is a matter to be considered seriously and undertaken with care. It has caused death, and you can readily appreciate the contra-indication in advanced heart-disease, pregnancy, arterial degeneration of old age, syphilis, etc., especially when the degeneration has resulted in aneurism. I do not understand that the danger, even in thoracic aneurism, is from the direct impingement of the tube, but rather from the straining and gagging of the patient and the resulting rise of blood-tension. The local gastric conditions, which contraindicate the passage of the tube, may be summed up in the one word ulcer, including any kind of ulcer, as of the peptic type or due to the breaking down of a cancer.

Obviously, most of the dangers here enumerated may be excluded in the present case. I shall, however, examine the mouth and throat to see that no false teeth are present, and that there is plenty of room for the passage of the tube through the fauces, and I shall listen also to the heart—which is beating normally, without murmur.

Patients usually prepare themselves for the ordeal by throwing the head backward, thinking thus to lessen the angle in the throat. This attitude, however, makes a compound curve in the esophagus, and really hinders the passage of the tube, so the patient must be directed to sit with the head upright. You will notice that I am holding the tube under the warm-water faucet. This is merely to lubricate the tube, and prevent the increased reflex from a cold body. The tube should be thoroughly cleansed and disinfected immediately after use, and put away in readiness for the next case. The patient is directed to "swallow hard whenever he gags," and, pushing gently on the tube, it soon passes till the fifty-five centimeter-mark is at the incisor teeth. At this depth, the tube works best in almost all adults with surprisingly little variation, due to difference in height.

I shall try to remove the gastric contents by expression, pressing my hand over part of the left hypochondrium and epigastrium, and directing the patient to breathe deeply, I follow each expiration with my hand and resist the expansion of the chest during inspiration. With this pressure, the gastric muscle is able to force some of the chyme out through the tube, and fifty c.c. are readily collected. I must confess to having been unusually successful with the method of expression in the present instance. I expect in most cases to be obliged to strip the tube with this roller-pump, and thus obtain the gastric contents by suction.

An inspection of the matter obtained shows the remains of bread, well masticated and softened, with little oil-globules representing butter, and partially disintegrated bits of meat. There is a slight rancid odor of butyric acid. There is undoubtedly some acetic and lactic fermentation with the butyric. There is no more than the normal slight amount of gastric mucus present. This stringy mass comes from the esophagus and is normal. I have known, however, of the diagnosis of gastric catarrh based on the presence of esophageal slime. Thus from simple inspection we are able to say that mastication and the rest of mechanical digestion are well performed, at least in the present instance, that there is a slight amount of fermentation, that there is no gastric catarrh, nor evidence of other organic lesion.

Litmus-paper shows the chyme to be acid as it practically always is, unless mixed with large amounts of bile, or blood, or with alkaline drugs. It must next be determined whether the acidity is due to free acid or to acid compounds. I have here a number of papers stained with anilin dyes, which change color in the presence of almost any free acid, certainly in the presence of those which we may find in the stomach contents. Tropæolin changes from yellow to magenta, gentian-violet to sky-blue, Congo red to blue, and benzo-purpurin from reddish to dark blue. Only the last two changes occur here, showing that there is free acid present, but to a slight degree only. To determine whether the free acid is hydrochloric, at least in part, I use a mixture of resorcin and cane-sugar, either a three per cent. watery solution of each (Boas' solution), or paper wet with such a solution and dried, or the crystals fused together. The test-paper is wet with the gastric contents and dried with heat, either over a gas or alcohol flame, or on a lampshade, or even a register, if the last is hot enough. Here you will see a distinctly reddish tinge, indicating, I believe, that an anilin dye is formed by the action of the hydrochloric acid on the aromatic ring contained in the resorcin. The same color-reaction occurs, you see, when the fused crystals of resorcin and sugar are heated in a capsule with a drop or two of gastric contents.

Next, let us ask, if carbohydrate digestion is normal? The filtrate from the chyme contains no starch, since iodin gives no color. The ordinary copper reduction-test shows that there is considerable sugar present. This sugar, by the way, is maltose, and not glucose, as was formerly taught. Up to three-quarters or an hour after a light test-meal, small quantities of starch may be present in the filtrate. Here, on account of a mistake, we are examining gastric contents nearly two hours after a meal. The test, to be rigid, should be made an hour after eating; to exclude minor disturbances of digestion, it should be made an hour and a half after eating. At this late

period of digestion we are making a very lenient test, so that apparently normal results cannot be taken positively, while deviations from the normal are all the more significant. Raw starch, which is commonly taken in the form of bananas, passes through the digestive juices till the pancreatic ferment is reached. Even cooked starch is not digested by ptyalin except in the liquid contents of the stomach—you see that the iodin-reaction occurs strongly in the unfiltered mass of chyme. While a moderate reduction of copper is normal, a heavy precipitate would indicate, not that carbohydrate digestion was unusually good, but that absorption was deficient, for the fully digested products of digestion should be absorbed from the stomach almost as soon as formed. In making these estimates, we must rely on experience and judgments, and, in fact, if carbohydrate food does not form acetic and butyric acids after gastric digestion is well established, that is after one hour P. C., we must be fairly well satisfied.

Nearly all albuminoid food enters the stomach coagulated by heat; if not, it is probably coagulated by the rennet ferment or ferments, as the casein of milk certainly is. Then, the hydrochloric acid forms an acid albuminate which is soluble, but which is coagulated by heat again, as you see by this test. Filtering out the albumin, the remaining clear liquid is floated over cold nitric acid, when a ring of albumose or partially peptonized albumin is formed. Normally, much of the albuminous food is digested only to this degree. Meat, however, is digested into true peptone, which I throw down by adding a fresh solution of tannic acid to the third filtrate. Tannic acid must not be used if starch is present, because the latter would give this same reaction; in the presence of dissolved starch, mercuric chlorid or some other reagent must be used in the third step. If the solution of tannic acid stands too long, gallic acid is formed, whose therapeutic value, you remember, is due to its inability to precipitate any form of albumin. I have described the digestion of albumins from a clinical standpoint. The precipitations here are about what we should expect normally, but we are applying the test two hours after eating instead of one hour after. At this stage of digestion, acid albumin should be peptonized almost as soon as formed, so that we may conclude that digestion is slow. The absorptive power of the stomach seems to be normal, as both sugar (digested carbohydrate) and peptone (digested albumin) are present in very moderate quantities. This is about the only reliable test for absorption, the elimination of potassium iodid through the mouth being utterly unreliable.

How are we to account for the slow digestion of albumin and the persistent, though slight, fermentation of carbohydrates? By the fact that very little hydrochloric acid is secreted. After a hearty meal this acid is taken up by albumin so that it may never be found free, but after a light meal, and especially at the time when digestion should be at its height, two hours after eating, there should be found in the chyme nearly the physiological proportion of acid in the clear gastric juice, that is, two per mille, or thereabouts. We need no quantitative estimation in this case, for the reaction with resorcin was slight, and even a tenth of the normal proportion of hydrochloric acid would not only yield a marked test with this reagent, but also with all the anilin dyes mentioned; whereas, free acidity was shown only by the more delicate tests with Congo red and benzo-purpurin.

There is an evident call for assisting the acid secretion of the stomach by administering a few drops of hydrochloric acid when it is most needed, about an hour after eating, and by urging the free ingestion of common salt on account of the contained chlorin. A better acquaintance with the case may suggest the need of rest from professional work, of positively tonic treatment, or of stimulating the glands of the stomach by using a bitter before meals, or preferably strychnin, which is both a bitter and a definite excitor of efferent nerves. Dieting, except so far as to avoid rich and useless preparations, should not be insisted on, except in extreme cases. A patient like the present one needs the appetizing effects of a variety of foods, and should not be limited to substances that are simply nutritious without being palatable.

CLINICAL MEMORANDUM.

A CASE OF HYPEROSTOSIS CRANII.[1]

By THEODORE DILLER, M.D.,
OF PITTSBURG, PA.;
VISITING PHYSICIAN TO ST. FRANCIS' HOSPITAL.

THIS remarkable and, fortunately, rare disease has been so recently described by Putnam[2] that I shall give only a very brief outline of a case now under my observation:

R. B., unmarried woman, aged thirty-one years; height 4 ft. 9 in. Father died of "brain-softening" (out of his mind five or six weeks); mother died of diabetes. Patient has four brothers and one sister, all healthy. Her head seemed to be somewhat misshapen from birth. When quite young, protrusion of her eyeballs was noted, and when she became old enough to go about the streets other children commented on this odd feature. Since childhood she has frequently been troubled with very severe headaches.

As a child, she was bright, cheerful, affectionate, possessed an unusually retentive memory, and excelled most other children of her age in her studies. Physically she was as active as she was mentally alert, and as she grew older concerned herself a great deal in the welfare of her brothers and sister.

When twenty-one or twenty-two years old, she had an attack of melancholia lasting about six months, from which she made a complete recovery. Up to this time the malformation of the head had increased. For the past ten years it has remained practically unchanged.

At the age of twenty-five she "slept" for a period of two days, and again at the age of twenty-seven. In 1895 she had an attack of mania lasting two or three weeks.

[1] Reported at a meeting of the Pittsburg Academy of Medicine, September 7, 1896.

[2] *Amer. Jour. Med. Sciences*, July, 1896. Bibliography, with "added" cases.

Complete recovery followed. She was admitted to the insane department of St. Francis' Hospital, February 1st last, in a maniacal condition. Her mental condition has now greatly improved.

In general appearance she is greatly undersized (not a family characteristic), has misshapen head, protruding, widely separated eyeballs, prominent nose, thick-set neck, and wide and sunken face; heavy, protruding, lower jaw

Fig. 1.

and large nose are characteristics which go to make up a most striking and grotesque figure. Her forehead is high. The cranium is flattened at the occiput, and appears as if pressed out from the left frontal eminence to the right occipital region. There is on the forehead a localized overgrowth of bone, three inches in diameter, which has its center one inch to the left of the median line. The fingers are short and stubby, the second and third on both hands being webbed up to the second phalangeal articulation. The second and third toes on both feet are completely and very closely webbed, while the third and fourth toes up to the last phalangeal joint on both feet are also webbed. Her skin is somewhat coarse and greasy, showing a number of folds. The hair is stiff.

The "stubby" and webbed condition of hands and feet and the dwarfish stature of the patient are features which,

Fig. 2.

together with the early appearance of malformation of the cranium, point most strongly to a teratologic defect of the trophic apparatus as the cause of the symptoms in this case, and lend support, as much as one case can, to this theory of the disease.

MEDICAL PROGRESS.

Bilious Malarial Fever with Hemoglobinuria.—As the result of a clinico-pathologic investigation Boisson (*Revue de Médecine*, 1896, No. 5, p. 360) arrives at the conclusion that the hemoglobinuria observed in certain forms of malarial fever is due to excessive destruction of red blood-corpuscles by the plasmodium malariæ of Laveran, in conjunction with functional insufficiency of the spleen and probably of other structures, such as the bone-marrow, believed to be concerned in the elaboration of the products resulting from the disintegration of the red cells. The icterus that accompanies the hemoglobinuria in intense attacks is of hematogenous origin.

The Treatment of Labyrinthin Vertigo.—At the recent Congress of the French Society of Laryngology, Otology, and Rhinology, Gellé (*Gaz. hebd. de Méd. et de Chir.*, 1896, No. 41, p. 485) discussed the subject of labyrinthin vertigo and the modes of treating the condition. Most commonly the affection is a result of lesions of the tympanum or its adnexa. Under these circumstances the treatment will be directed toward exhausting the tympanic cavity, freeing the labyrinth by means of politzerization, catheterization, rarefaction, etc. If the morbid changes are chronic in character surgical intervention will be called for. In case of hemorrhage into the tympanum leeches should be applied to the mastoid region, a suppressed bloody discharge reëstablished, a drastic administered and a milk-diet observed, with rest and injections of ergotin. If hyperemia of the tympanum exist, paracentesis should be practised, followed by irrigation with tepid water to facilitate the flow of blood. Later, hypodermic injections of pilocarpin may be employed; or iodids may be administered; gouty patients should be given colchicum, or colchicin, or sodium salicylate. In cases of cardiac or renal disease a milk-diet and intestinal revulsives render a useful service. If the labyrinthin hyperemia be active the same measures are employed as in the case of hemorrhage. If the hyperemia is passive and due to central circulatory disturbances, remedies suitable for these conditions are indicated (such as a milk-diet, strophanthus, etc.), with the avoidance of hot baths and various thermal excitants. Bromids and arsenic also are indicated. The cold douche is applicable at the onset of the passive and neurasthenic forms, with the hope of preventing their full development. If the vertigo be due to local anemia, it is best treated by means of tonics—iron, iodids, kola, caffein. In case of inflammation of the internal ear, pilocarpin may be employed at first; quininand strychnin also are useful. If a syphilitic origin is suspected, specific treatment should be employed. Quite often labyrinthin vertigo is due to mechanical causes—a blow, deglutition, centripetal compression, mastication, congestion, etc. The best remedy is quinin sulphate—given at first in doses of three grains, and after the lapse of a few days of four grains, thrice daily. After an intermission the medication is resumed, notwithstanding ringing in the ears. In addition general sedative treatment may be employed. Air-douching and paracentesis of the tympanum may af-

ford relief. In nervous patients cold douching accelerates recovery. When infectious diseases and toxic conditions are attended with vertigo and deafness, appropriate measures should be directed against the constitutional condition. Vertigo is often a symptom of sclerosis, even in advance of deafness, and under these circumstances it may be supposed to be of gastric origin. Vertigo is often due to uterine, hemorrhoidal, pulmonary, and psychic disorders. The labyrinth, like a monometer, responds readily to variations in blood-pressure and nervous impressionability, and manifests its disturbance by vertigo, roaring in the ears, hallucinations.

The Malarial Cachexia and its Treatment.—At a recent meeting of Société de Thérapeutique, Vidal (*l'Union Médicale*, 1896, No. 24, p. 284) related the results of a clinical study of the malarial cachexia, of which the most conspicuous manifestations are pallor, especially of the face, with a bluish tint of the conjunctivæ, respiratory difficulty, edema of the legs, puffiness of the face, and distention of the abdomen, with or without ascites. The patients complain of palpitation, of cyanosis, of coldness of the extremities, and of tremor; and they are apathetic, indisposed to activity, and depressed, and suffer from profound lassitude, physical and moral. Physical examination discloses, in addition to hypertrophy of spleen and liver, pronounced hypertrophy of the heart. On auscultation, the heart-sounds are feeble and irregular, and the pulse frequent; often, instead of a systolic bruit at the apex, a murmur may be heard following the muffled second sound. These signs are attributed to a myocarditis, which, in turn, is made responsible for the symptoms of the malarial cachexia. From this point of view treatment has been directed to the heart, diuretic medication being systematically employed. In those who can tolerate it, an absolute milk-diet yields excellent results. Often, however, solid food must be allowed. If the heart is feeble or arrhythmic, a dose of fifteen drops of a $\frac{1}{10}$ per cent. solution of crystallized digitalin is given at the beginning, followed by oxymel of squill, and the salts of potassium. Each morning, for ten or twelve days, the patient takes, besides, a sixth of a grain of calomel. Under this plan of treatment the excretion of urine increases, the edema disappears, the color brightens, the action of the heart improves; and in the course of from two to six weeks the patients are free of their cachexia, and prepared for the treatment of their chronic malarial infection with arsenic, phosphates, hydrotherapy, etc.

A New Method of Preserving Anatomic Specimens.—At a recent meeting of the Société de Biologie, Melnikoff-Razvedenkoff (*Médicine Moderne*, 1896, No. 47, p. 376) described a new method of preserving anatomic specimens. The fresh organ is placed for twenty-four hours upon a bed of cotton saturated with a forty-per cent. solution of formaldehyde. Then for six or eight hours it is kept in ninety-five per cent. alcohol. Finally, it may be preserved in a solution consisting of distilled water, 100; potassium acetate, 30; glycerin, 60; or in a two-per cent. solution of formalin; or in alcohol; or in a preparation consisting of gelatin, 100 grams, dissolved in 600 grams of hot water, with the addition of 350 c.cm. of a solution of potassium acetate, then filtering and adding 700 c.cm. of glycerin.

The Metabolic Changes of Acute Yellow Atrophy of the Liver.—Richter (*Berliner klinische Wochenschrift*, 1896, No. 21, p. 453) reports two cases of yellow atrophy of the liver, both in women, and both developing in the sequence of syphilitic infection, in which he found, in contravention of general belief, no deficiency in the excretion in the urine of urea, and no increase in the excretion of ammonia. There was also an increase in the elimination of uric acid and allied substances—the so-called alloxan-bodies. The total amount of nitrogenous elimination was augmented. These results would seem to show that urea is formed in other organs than the liver in greater degree than has heretofore been believed, and that in case of destructive disease of the liver the function of urea-formation is taken up in increased measure by those organs.

THERAPEUTIC NOTES.

Orphol as an Intestinal Antiseptic.—E. Chaumier (*Therapeutische Wochenschrift*, 1895, 48) says that of all intestinal antiseptics B. naphthol has so far given the best results. Its unpleasant taste, odor, and the burning sensations in the stomach, to which it gives rise, render it difficult of administration, especially to children. Many substitutes, such as betol, salol, and salicylate of bismuth, have been employed, but found unsatisfactory.

In the intestinal antiseptic orphol we have a remedy which gives the same good results as are obtained from the use of B. naphthol, without its drawbacks. It does not produce any burning sensation, and is easily administered, even to children. In the diarrhea of children it is especially serviceable. The dose varies from one to five grams per diem for children and infants. It may be given either with milk or honey. The noticeable good effects in these cases are that the stools lose that fetid odor, watery character, and green color. The dose for adults is from five to ten grams a day. Good results have been obtained from its administration in the diarrhea of phthisis and typhoid fever in adults. In phthisical patients the colicky pains have been known to vanish, the number of stools to diminish, and the appetite to improve considerably by the use of orphol.

For Pruritus of the Scrotum.—

℞	Carbolic acid	ʒ iv
	Glycerin	f ʒ ii
	Alcohol	f ʒ v
	Water	f ʒ viii
	Mix.	

Into a glass of water as hot as the patient can bear is poured from one to four tablespoonfuls of this solution, and with the fluid gauze is saturated in which the scrotum is enveloped. The dressing is completed by means of a rubber suspensory.—Brocq, *Semaine Médicale*, 1896, No. 30.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

Subscription Price, including postage in U. S. and Canada.

Per Annum in Advance	$4.00
Single Copies	.10
With The American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, OCTOBER 24, 1896.

A WESTERN DIPLOMA-MILL.

"Annual Announcement of the Illinois Health University in Chicago for the year 1896" is the ambitious title of what appears from the circular to be a most barefaced and outrageous swindle. Immediately beneath the title is the distressing information that the institution is incorporated under the laws of the State of Illinois. From the amount and character of abuse that is poured out against the Illinois State Board of Health, we judge that this "University" has come into violent contact with the latter and has received such a serious blow that it can scarcely set itself right before even an undiscerning public.

The first page of the announcement contains a quotation from the "Writings of an Eminent Physician." We cannot place the excerpt positively, but we believe that it is extracted from the writings of an eclectic surgeon who has hitherto been able to circulate the productions of his pen only among his fellow paranoiacs in the Ward's Island asylum, and some of it has recently illumined the pages of "The Last Writings of a Paranoiac."

The photographs of the professors occupy a conspicuous place in the announcement, and if one may judge from appearances and costume, the majority of them have not been away from Russia, Poland, and Van Diemen's Land long enough to have been forgotten.

The milk in the cocoanut, however, is reserved to the last, and consists of advice to prospective students, course of study, and requisites for graduation, and it is to these that we wish particularly to call attention. In just these words it says: "We are opposed to the absurd, unjust, and unreasonable rules compelling students to attend a medical college before granting them the degree of M.D., and we are prepared to legally graduate men and women at home without even ever having seen them, for the sum of $75." Those who wish to apply for their degree must furnish evidence that they are of moral character (probably to satisfy the conscientious scruples of the Reverend, who is the "Prof." of anatomy and physiology) and that they have conducted a safe (*sic*) practise for a term of years. The announcement naively adds that there are many men and women in this country who are desirous of appending M.D. to their names, so as to increase their earning capacity, but they are prevented from doing so by lack of funds. To all such the advice is given that they send a dollar a month for books, to which they should apply themselves for an hour each evening during the winter, and in the meantime that they gather together the necessary $75 before spring, when the University, as an act of righteous duty and as a reward of merit, will legally confer on them the degree of doctor of medicine.

The books which such students are urged to buy are: "The Tricks, Deception, and Frauds Practised in the United States by So-called State Boards of Health and State Boards of Medical Examiners;" "Consumption; How to Beat it Scientifically;" "The Ridiculous and Absurd Means Recommended by Medical Monopoly Doctors;" "The Duty of the Clergy to Assist in Repealing Such Infamous Medical Laws as that Now in Force in Illinois." These titles will convey an idea of the character of the studies which students are requested to pursue.

It would seem unnecessary to make any com-

ment on what is so openly fraudulent as this diploma-mill. Yet we are not unmindful that there are in this vast land, as the circular truthfully says, those who would like to attach M.D. to their names, but who are prevented from so doing on account of mental and financial shortcomings. It is for these and for the originally dishonest and ignorant that the circular is intended.

There should be some means of enlightening legislative bodies who are responsible for the legal existence of such pedagogic and moral monstrosities as the Illinois Health University. They should be awakened to the fact that by chartering such an institution, they are as culpable in jeopardizing and menacing the welfare of the public as they would be if they legislated quarantine out of existence and so let in some horrible plague. In the absence of such illumination, it behooves medical men, the country over, to be watchful that no one of their community, be he ever so devoid of principle, is dragged into the net of this legalized medical cormorant of Chicago.

RECENT PROGRESS IN THE KNOWLEDGE OF HEREDITARY SYPHILIS.

IT has not yet been demonstrated that syphilis is of bacterial origin, but our knowledge of this far-reaching infection has been greatly amplified and modified by clinical and pathological discoveries, which have been made while studying the nature and course of other infectious diseases. It is now definitely known that in many cases there is an intimate association or symbiosis of many morbid states and conditions, and that syphilis pathologically modifies other morbid conditions. In its turn, its pathological developments may in like manner be acted upon by other diseases. These facts have been well presented in a short essay on hereditary syphilis and tuberculosis by Hochsinger ("Verhandlungen der Deut. Dermatologischen Gesellschaft," Vienna, 1894, pp. 335 *et seq.*), which will undoubtedly lead, in time, to a revision and recasting of all our knowledge of the pathological anatomy of inherited syphilis. He gives the history of three cases in which the symbiosis of syphilis and tuberculosis was positively proved, and these histories quite clearly show that the latter infection was the predominating one. Had not these cases been so thoroughly studied, both histologically and bacteriologically, they would, like many thousands before them, have been incontinently set down as typical examples of heredity with visceral lesions.

As a result of these studies and observations, Hochsinger concludes that a mixed infection of hereditary syphilis and tuberculosis may be found in the very youngest children, and that thus a double infection may be simultaneously transmitted at conception. These observations also show that all nodules, caseous or otherwise, found in hereditarily syphilitic infants should not be pronounced to be syphilitic gummata until it is shown that they do not contain the tubercular bacillus. In hereditarily syphilitic pneumonia there is true interstitial granulation-tissue infiltration, with perivascular cell-proliferation into the lung-parenchyma, and no tubercular bacilli.

The foregoing considerations very clearly emphasize the facts that in many bad cases of hereditary syphilis there is, in all probability, a synchronous tubercular infection, and that no nodules found in the viscera, and, indeed, we may add, in the bones, joints, and skin of these subjects, should be pronounced to be gummata until the influence of tuberculosis has been excluded. Diagnoses which are based on macroscopical appearances are not reliable, since to the eye the lesions of syphilis very often resemble those of tuberculosis in a striking manner. In some nodules there has been found evidence of the action of both syphilis and tuberculosis.

In earlier days we were accustomed to speak of the cause of death of infants and children hereditarily syphilitic as due to congenital want of vitality, particularly when, at the autopsy, we found no visible involvement of an important organ. Pavloff (*Annales de Dermat. et de Syphiligraph.* July, 1895) concludes that vessel-changes are the cause of death of most hereditarily syphilitic children, and he makes the pertinent suggestion that this extensively distributed morbid condition indicates the great necessity of a general systematic treatment. It is important, in this connection, to remember that Mracek found in the viscera of eighteen hereditarily syphilitic children hemorrhages of such severity that they

constituted the active cause of death. As bearing upon Pavloff's conclusions, Bar and Tissier (*Ibid.*, pp. 1156 *et seq.*, 1895), at the autopsy of a child at term, whose parents were victims of active syphilis, found pathological changes in the veins and arteries throughout the entire body.

The histories of cases reported by Murri, Schumacher, and Goetze have shown that there is a probable etiological relation between acquired syphilis in some subjects and paroxysmal hemoglobinuria. Recent observations seem to show that the morbid combination may occur in the course of hereditary syphilis. Courtois-Suffit (*Médecine Moderne*, No. 18, March 2, 1895) reports the case of a four-year-old child born of syphilitic parents, presenting characteristic lesions of the tibia, who, during two years (third and fourth of life), suffered from attacks of hemoglobinuria, at first when exposed to severe cold, and later on even when the temperature was not low. Treatment by mercurial inunctions and the ingestion of potassium iodid caused improvement in the osseous lesions and allowed the child to escape any attacks of hemoglobinuria during a severe winter. Comby, in a later communication (*Ibid.*, No. 18, March 6, 1895), claims that he had previously pointed out this symptom as being etiologically related to hereditary syphilis. Goetze (*Berl. klin. Wochenschrift*, 1884, p. 716) reported the case of a child, nine years old, who presented structural evidences of hereditary syphilis, but whose medical history was unknown, who suffered from hemoglobinuria. The study of this interesting question has only just begun, it being yet in the stage of case-reports.

A like condition prevails as to the clinical history and the pathology of the changes and disorders of kidneys in hereditary syphilis. Hoch (*Wien. Med. Presse*, 1894, p. 1697) details the case of a typical syphilitic infant, three months old, in which, while favoring the view that the nephritis was caused by syphilis, he suggests that perhaps it was due to the action of mercurials. In this case the hiatus consists in the absence of an autopsy and of histological findings.

In a case reported by Massalongo, we find more satisfactory data (*Arch. per Scienze Mediche*, Ix and ii, 1895); the infant was six months old, born of a syphilitic mother, and it presented typical lesions. Before death it suffered from albuminuria, edema, convulsions, and uremic coma. Histological examination of the kidneys showed well-marked changes in the arteries—endarteritis and periarteritis—and thromboses, extensive interstitial nephritis, and great increase in the connective tissue, which compressed the glomeruli and produced sclerosis of the organ. The lesions resembled those of late nephritis in acquired syphilis of adults. Massalongo thinks that these visceral changes began in intra-uterine life.

With the expansion of our knowledge of syphilis as a chronic infectious disease, it seems that many surprises are in store for us. Cases reported by Hutchinson, D'Ornellas, Morgan, Elsenberg, and myself, have shown very clearly that Raynaud's and Morvan's diseases may occur in the course of acquired syphilis, and that the latter infectious process is, in all probability, etiologically related to them. Krisowski (*Jahrbuch f. Kinderheilkunde*, vol. xi, pp. 57 *et seq.*) described a well-observed case of hereditary syphilis, in which symmetrical gangrene was a prominent symptom. Under mercurial inunctions and the internal use of potassium iodid a cure was promptly brought about. Here, then, is another subject for study in the protean drama of hereditary syphilis.

Robert W. Taylor, M.D.

ECHOES AND NEWS.

A Boy's Cast-off Skin.—A Florida paper reports that an eight-year-old boy has shed his skin. That on the face came off separately, but from the neck down the cuticle moved off by way of the hands and feet without breaking.

Dr. T. Colcott Fox.—The New York Dermatological Society held a special meeting, October 19, at the New York Academy of Medicine, in honor of Dr. T. Colcott Fox, the distinguished dermatologist of London. The informal social functions were not the least enjoyable feature.

St. Luke's Consecrated.—The new buildings and chapel at St. Luke's Hospital, New York, at West 113th street and Morningside Heights, were consecrated October 17th by Bishops Potter of New York, Littlejohn of Long Island, and Huntington of Central New York.

The Jews and the International Medical Congress.—The Exhibits' Committee of the Twelfth International Con-

gress has issued a statement saying, that the Minister of the Interior has authorized the arrival at Moscow of foreign Jewish savants under the same conditions as other foreigners.

King William's Touch.—*The British Medical Journal* concludes an editorial on "Psychic Vaccination" by giving to those who look to hypnotism for healing, the advice of King William to those who came to him to be touched for the king's evil, "God give you better health and more sense."

Antipodean Legislation.—The New Zealand Government has introduced a bill which makes it the duty of the master or owner of a vessel to prevent any one affected with tuberculosis from embarking for New Zealand. Should a tuberculous patient land, he and the master are liable to a fine of £10.

Paucity of Medical Men in Russia.—M. Anitchkoff, Under-Secretary of the Ministry of Education, says that in the whole Russian Empire, with a population of 110,000,000, there are only 18,334 qualified practitioners. This gives a ratio of one practitioner to 6000 inhabitants, while in Germany the proportion is one to 3000, in France one to 1800, and in England one to 1600.

Resigns From the Army.—Dr. John B. Hamilton, Surgeon-General of the United States Marine Hospital, stationed in Chicago, has sent in his resignation to President Cleveland. Some time ago Dr. Hamilton was ordered to the Marine Hospital at San Francisco by the War Department. He objected to being transferred, and made an official protest. This protest was overruled.

A New Medical Monthly.—*Moody's Magazine of Medicine* is the name of the latest addition to the long list of American medical periodicals. It is edited by Raley H. Bell, M.D., and published in Atlanta, Ga. The plan and policy of the journal as announced in the prospectus is to interest the rank and file of the medical profession, particularly throughout the New South and West. We doubt the propriety of combining the features of a family magazine with those of a medical journal, and we question the good taste of such a frontispiece as appears in the first number.

Degenerative Changes in the Brain-cells of the Non-insane.—Dr. Robert Hutchison, in *Edinburgh Hospital Reports*, from a histological examination, finds that the brains of the sane and the insane show similar changes. With the exception of general paralysis of the insane there is little that is special to the insane pathologically. Pigmentation-cells, for example, are to be found in all sorts of people, especially after middle life. He throws doubt on the association of vacuolation of cells with epilepsy. He falls back upon the nebulous hypothesis of inherent instability of the brain.

The Marine-Hospital Service.—There will be held in Washington, D. C., on February 3, 1897, a competitive examination of candidates for appointment to the position of assistant surgeon in the United States Marine-Hospital Service. Candidates are required to be not less than twenty-one years of age, and no appointment is made of any candidate over thirty years of age. They must be graduates of a reputable medical college and furnish testimonials as to character. Full information may be obtained by addressing the Surgeon-General of the Marine-Hospital Service, Washington, D. C.

The Syracuse Medical College.—Dr. Stephen Smith of New York spoke of the new Syracuse Medical College, in his address at its opening, as follows: "The college of medicine of the Syracuse University is the child of a healthy parentage. It is the legitimate offspring of two medical schools that, in their day, made a most honorable record—the College of Physicians and Surgeons of Western New York, and the Geneva Medical College. It is gratifying to state on this occasion that this college has been one of the first to adopt a graded course of instruction, which is the most important reform yet made in the method of teaching. This has been followed by class recitations, instead of lectures, in teaching the practical branches—a change of the greatest value to the individual student. Finally, it is about to extend the term of study to four years and thus place itself in the front rank of the most advanced colleges in its methods of instruction."

Parasitic Origin of Trachoma.—*The Lancet*, September 12th, makes mention that Professor Guarnieri of the University of Pisa has published in the July number of the *Clinica Moderna* of Florence a preliminary account of his researches into the pathogenesis of trachoma. In fourteen hospital-patients he has found in the detritus obtained by energetic "raclage" of the trachoma-granulations some very small round bodies capable of being intensely stained, preferably with a two per cent. solution of magenta-red in water. They can then be recognized with a magnifying power of only ninety diameters, although they are so small that the diameter of some is between a third and a half of that of a red blood-corpuscle. Professor Guarnieri is inclined to suspect that they are of a parasitic nature and belong to the class of *Blastomycetes*, but he has not yet succeeded in cultivating them, and is still pursuing the investigation.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income of one year of the bequest of the late Señor Alvarenga, and amounting to $180, will be made on July 14, 1897, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the Secretary of the College on or before May 1, 1897. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in the possession of the College; other essays will be returned upon application within three

months after the award. The Alvarenga Prize for 1896 was not awarded.

National Sanitary Association.—The second annual convention of this society was held October 13th to 15th, at Brooklyn. Among the papers presented was one on "The Municipal Control of the Consumptive," which was read by Dr. T. C. Craig, U. S. N; and one on "The Work of the Division of Contagious Diseases of the New York Health Department," which was read by Dr. Charles S. Benedict, chief of that department. Dr. E. A. Wilson, health officer of Meriden, Conn., spoke on the advisability of leaving the question of disinfection to the attending physician, although he did not favor too much reliance on them in that respect. He alluded to the fact that he found no difficulty in keeping track of cases of contagious diseases in the city or town districts under his control, but it was in the country where the danger lay. Dr. A. N. Bell discussed the value of isolation hospitals, holding the opinion that they are of minor importance. Excepting in the case of small-pox, he believed there was no evidence of the aerial distribution of contagious diseases. He believed, further, that there was no positive evidence of any disease crossing the street except small-pox. Dr. E. H. Bartley read a paper on the educational duties and privileges of Boards of Health, closing with the practical suggestion that there be a journal established which shall be the joint product of all the State Boards of Health of the country.

SPECIAL ARTICLE.

ANESTHESIA JUBILEE.

PUBLIC EXERCISES HELD IN THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON, OCTOBER 16, 1896, IN COMMEMORATION OF THE FIFTIETH ANNIVERSARY OF THE FIRST PUBLIC DEMONSTRATION OF SURGICAL ANESTHESIA.

[Special Report to the MEDICAL NEWS.]

THE trustees and visiting staff of the Massachusetts General Hospital with due consideration for the importance of the event to be commemorated, arranged for the celebration of the fiftieth anniversary of the discovery of surgical anesthesia. Large imposing invitations, printed on parchment paper, were issued and distributed among the prominent members of the profession throughout this country and in Europe. The invitations happily avoid any discrimination between the various claimants to the honor of the discovery. They read as follows: "Commemoration of the Fiftieth Anniversary of the First Public Demonstration of Surgical Anesthesia at the Massachusetts General Hospital, Boston, October 16, 1846. The honor of your company is requested October 16, 1896." At the top of the invitation is the seal, and at the bottom the picture of the hospital as it appeared in 1846.

In this broad spirit the invitations were issued, although in the course of the exercises there was no concealing the fact that in the special event commemorated Morton, who gave the anesthetic, and Warren, who assumed the responsibility of allowing it to be given to one of his patients and who performed the operation, were the prominent actors in the discovery.

The guests were received by the committee in the old amphitheater, where ether was first given. It was arranged to conform as nearly as possible with the appearance it presented on that memorable morning in 1846. The original operating-table was in position, the same instruments were there, and the glass globe, through which the ether was administered. In an adjoining case was the old record-book in which the history of the patient was recorded and the account of the operation.

The book was opened to the page telling the story of this wonderful surgical operation of October 16th, but was dated Friday, September 25th, the day of the admission of the patient. He was Gilbert Abbott, a printer, who had a tumor of the neck. After a preliminary description of the case, the report goes on to say: "This case is remarkable in the annals of surgery. It was the first surgical operation performed under the influence of ether. Dr. Warren had been applied to by Dr. Morton, a dentist, with a request that he would try the inhalation of a fluid which he said he had found to be effectual in deadening pain during operations on the teeth. Dr. Warren having satisfied himself that the breathing of the fluid would be harmless, agreed to employ it when an opportunity presented, and determined to use it on this patient.

"Before the operation began, some time was lost in waiting for Dr. Morton, and ultimately it was thought he would not appear. At length he arrived, and explained his detention by informing Dr. Warren that he had been occupied in preparing his apparatus. This apparatus he then proceeded to apply, and after four or five minutes the patient appeared to be asleep, and the operation was performed as described.

"To the surprise of Dr. Warren and other gentlemen present, the patient did not shrink nor cry out, but during the insulation of the veins he began to move his limbs and utter extraordinary expressions, and these movements seemed to indicate the existence of pain, but after he had recovered his faculties he said he had experienced none, but only a sensation like that of scraping the part with a blunt instrument, and he ever after continued to say he had not felt any pain."

The guests were composed almost exclusively of members of the profession, but special honors were conferred upon Mrs. Morton, the widow of the discoverer, and members of her family, who were present.

Dr. John Collins Warren opened the formal exercises by reading the following cablegrams, two of a number, showing the widespread interest in the affair:

"CHRISTIANIA, Sweden.

"Trustees and Staff Massachusetts General Hospital, Boston:

"Best congratulations on fiftieth anniversary.

"CÆSAR BOECK."

"Boston Massachusetts General Hospital, Collins Warren:

"The Moscow Surgical Society, at a special meeting held in honor of the fiftieth anniversary of the introduction of anesthetics, celebrates the memory of Morton and Simpson, the great benefactors of mankind. It greets

the committee, and wishes it every success in its labors on behalf of science, which knows no geographical boundary.

"DIAKOW, President.

"WARNECK, Secretary."

Mr. Charles H. Dalton, president of the trustees of the hospital, then read an address of welcome, in which he said:

"It is my privilege on behalf of the corporation of the Massachusetts General Hospital to welcome you here to-day as guests of this venerable institution. Though somewhat less than a century old, the hospital is one of the earliest in the country. It has long passed its infancy and youth, and has reached a period in its life already rich in history and traditions.

"For three generations the institution has never failed to have at its service the highest professional skill in all its constantly growing departments and scientific development, and the sympathy and confidence of the public. I do not refer to this record as being in any degree peculiar to this hospital. It is, in general, the common history of all similar institutions, illustrating, perhaps, in the most sincere form, man's humanity to man. If, however, we could imagine all this record erased, if all the intelligence of the physician, the skill of the surgeon, the watchfulness of the nurse, the benefactions of the public, and, more than all, the saving of life and relief of suffering were as nought, there would still remain one page in its history which of itself alone would be more than a recompense for the loss of all the rest, inasmuch as of what was inscribed thereon, the whole world has been the beneficiary, and, incidentally, has raised the name of the Massachusetts General Hospital to an honorable distinction at home and abroad. Fifty years ago to-day in the operating-theater, sulphuric ether was first given for the prevention of pain to a patient undergoing a capital operation. This application was made by Dr. W. T. G. Morton. The experiment was a success.

"Of the infinite blessings which followed this, the greatest gift of the century to mankind, of its contributions to the relief and safety of suffering humanity, to the surer confidence and success of the physician and surgeon in his efforts for the saving of human life, and in scientific investigation, it is not my function to speak. These themes are for the scholar and scientist.

"I have simply to express to you the cordial welcome of the corporation to this celebration of the fiftieth anniversary of the first surgical operation under which the patient suffered no pain, no discomfort, no anxiety. The occasion is unique."

The first paper on the program was read by Dr. Robert T. Davis of Fall River, who was present when Dr. Morton made his famous experiment.

Dr. Davis said: "Fifty years ago to-day occurred the first authentic, unquestionable, public exhibition of anesthesia during a surgical operation. As one of the few surviving witnesses of that memorable event—the most important in surgical, and one of the most important in human history—I have been invited to state my recollections of the incidents attending it, and gladly comply with the request.

"The operation in which the anesthetic was administered was performed in the surgical amphitheater of the Massachusetts General Hospital by Dr. John C. Warren, in the presence of a number of distinguished surgeons and physicians, including Dr. Hayward, the elder Dr. Bigelow, one of the wisest and greatest men who have adorned our professorship with their multifarious gifts and accomplishments, and his celebrated son, not then arrived at the zenith of his fame. The Harvard medical class was also present.

"After some delay, Dr. William Morton appeared with his apparatus, when Dr. Warren addressed the medical class, which had not been previously notified of his proposed experiment, stating in substance that there was a gentleman present who claimed that he had discovered that the inhalation of a certain agent would produce insensibility to pain during surgical operations with safety to the patient, and he added that the class was aware that he had always regarded that condition as an important desideratum in operative surgery, and he had decided to permit him to try the experiment.

"The patient, who was a young man, was suffering from a vascular tumor of the neck on the left side, occupying the space from the edge of the jaw downward to the larynx, and from the angle of the jaw to the median line.

"Dr. Morton proceeded to apply to the lips of the patient a tube connected with a glass globe. After the inhalation had continued four or five minutes, he appeared to be asleep, and the operation was commenced and completed without further inhalation of the ether. The operation consisted of an incision about three inches in length over the center of the tumor, and through the skin and subcutaneous cellular tissue, and the removal of a layer of fascia which covered the enlarged blood-vessels. A curved needle, armed with a ligature, was then passed under and around the tumor, and considerable compression was employed. During most of the time occupied by the operation the patient gave no sign of sensibility, and appeared to be sleeping quietly. A short time before its completion he moved his head, body, and limbs, and muttered words which I could not hear distinctly, but upon recovering consciousness he declared that he had suffered no pain, but simply a sensation like scraping the parts with a blunt instrument.

"The exhibition of the anesthetic was admitted by those present to be a complete success. The operating surgeon expressed his satisfaction in these emphatic words: 'Gentlemen, this is no humbug.' From that time forward it became the practise to employ it at the hospital in all operations of importance.

"Dr. Morton continued to administer it until it was proved that it could be easily and safely administered by others. The apparatus which he had used in the first and a few subsequent operations was soon abandoned as unnecessary and a concave sponge was substituted."

The next paper was on

SURGERY BEFORE THE DAYS OF ANESTHESIA,

by JOHN ASHHURST, M.D., LL.D., of Philadelphia.

(See MEDICAL NEWS, October 17, p. 433.)

David W. Cheever, M.D., of Boston, then took for his topic:

WHAT ANESTHESIA HAS DONE FOR SURGERY.

He said:

"What victim of surgery who, under ether, sinks into a calm and dreamless sleep, during which his abdomen can be cut open, his bowels taken out, handled, and replaced, his nerves cut, his veins or arteries tied, and his skin sewed up, and who is made so absolutely oblivious as to ask on awakening: 'Are you not ready to begin?' but concedes with gratitude, on realizing the result, that this is the greatest discovery ever made for the happiness of mankind? In proportion, as anticipation is worse than reality, must be estimated the mental relief brought about by anesthesia.

"To dread the knife, to shrink from an operation, to fear pain, is there a more universal instinct? It is next to the vital instinct of self-preservation. What iron will, what previous agony must induce that fortitude which can bring the sufferer to lie down and be cut without stirring! All this is annulled by anesthesia. Anticipation is done away with, pain is prevented, shock is reduced.

"The patient consents to operation earlier; he does not wait until life becomes unbearable, but calmly contemplates surgery as the natural and easy channel of relief. Hence his chances of benefit from an operation are much increased; he averts destructive processes, shortens disease, is more likely to recover. So much is done for the patient.

"To the surgeon anesthesia gives the patient asleep, motionless, senseless. He need not hurry; he need not sympathize; he need not worry; he can calmly dissect, as on a dead body, heedful only that the etherizer is competent, the breathing and pulse watched, the operation not prolonged beyond the verge of exhaustion. The surgeon, then, can do better work; he can be more careful; he can pause and consider; he can choose his steps; he can be deliberate, if not dexterous. He can even summon the aid of the pathologist and his microscope, who, in ten minutes, while the patient sleeps, can decide the nature, the innocence or malignancy of the tumor he is removing. It is also just to believe that the moral fiber of the surgeon is less strained; judicial callousness is no longer called for; he need not steel his heart, for his victim does not feel. The tyranny of misguided conscience drove the inquisitors of the Middle Ages to rack the joints apart; so, too, the surgeon was formerly obliged to use the rack to tire the muscles and disrupt the capsule to reduce a dislocation. Now, anesthesia relaxes the muscles and manipulation rolls the bones into the socket."

ANESTHESIA IN OBSTETRICS,

was next presented by J. P. Reynolds, M.D., of Boston. He said:

"In operative obstetrics, in the high and difficult use of instruments, in the introduction of the hand for version and extraction, anesthesia resembles at all points its use in the graver procedures of general surgery.

"Would that any words of mine could bring home, as I feel it, the inestimable blessing of ether in all labor, silence groundless excuses for its neglect, and so rouse professional interest that no one should lightly forbid it to any woman in childbed!

"Only one rule governs its use. Whenever the attendant sees that the woman's endurance of pain begins to tell upon her patience and courage, the moment for ether has come. It is to be kept up so long as this need lasts; no longer."

W. H. Welch, M.D., LL.D., of Johns Hopkins University, then read a paper on

THE INFLUENCE OF ANESTHESIA UPON MEDICINE.

He claimed that in all the centuries there had been no discovery comparable to any of these great discoveries of the past one hundred years, namely, the discovery of vaccination by Jenner, the discovery of anesthesia by Morton, and the discovery of antisepsis by Lister.

His address was a plea for vivisection and animal experiment, as absolutely necessary for science. In these experiments, he said, artificial anesthesia is an important factor, and many physiological experiments could never have yielded the results they did if it were not for the use of anesthetics, especially when it is necessary that the animal should survive the experiments.

The discovery of anesthesia was made in the only way it could possibly have been made, *viz.*, by scientific animal experimentation. Sir Humphry Davy and Morton both experimented on dogs. It was a triumph of the experimental method. Later animal experimentation with anesthetics has revealed a great amount of knowledge not obtainable in any other way. The gentle killing of bacteria preserves in their bodies certain chemical substances which undergo changes in their sudden death. The great progress which characterizes the history of medicine for the past fifty years, is due entirely to animal experimentation.

The last paper was read by Charles McBurney, M.D., of New York, on

THE SURGERY OF THE FUTURE.

He said:

"We worship to-day at the shrine of the Goddess Anesthesia, whose gentle sway over the surgical world of all civilized countries has so beneficently displaced the reign of terror which existed only two generations ago. What anesthesia has done for surgery has been already most eloquently told, and we all realize that without it the best of modern work would be impossible. It seems but yesterday, and yet it is a matter of history, that the wonderful discovery of the aseptic treatment of wounds was given to us, through whose agency countless thousands of human lives have been preserved. Through these two discoveries, surgery has become a gentle art; for the agonies of operations and the fatal diseases of wounds have given way to a painless sleep, and an awakening to a safe recovery. And bacteriology, which in its infancy gave birth to aseptic surgery, has penetrated with its brilliant light a darkness which our predecessors believed would last forever.

"The surgeon can to-day prevent the entrance of sepsis through either accidental or artificial wounds, but in the

presence of sepsis already in the system the surgeon stands practically helpless. Infusion of warm saline solutions into the blood-vessels gives promise of a time when we shall withdraw poisons from one part of the body and inject life-giving fluid at another point. Already we can pronounce the dictum that death from hemorrhage is unnecessary. Saline injections not only stop the hemorrhage, but fill the depleted blood-vessels, stimulate the heart, and renew the functions of life.

"The surgery of the future attracts to its enthusiastic study and practise finer and finer men, in whose hands we may safely leave the development of our science.

"A single glance at the faces of the students who collect daily in your operating-room will show you what a change has occurred in the last twenty-five years. For this, too, we must be ever grateful to anesthesia, which, in removing the torture of surgery, has robbed it of what repelled many sensitive natures.

"And the science of asepsis, by rendering complete success in surgical work possible, will excite the most devoted enthusiasm from many scientific men, who soon would have become sick at heart over the failures of former times.

"What more attractive opportunity could possibly exist than will be offered by surgery to the well-educated, refined, able, and ambitious student?"

An original poem, entitled "The Birth and Death of Pain," was then read by S. WEIR MITCHELL, M.D., of Philadelphia.

Forgive a moment, if a friend's regret,
Delay the task your honoring kindness set.
I miss one face to all men ever dear;
I miss one voice that all men loved to hear.
How glad were I to sit with you apart,
Could the dead master use his higher art
To lift on wings of ever lightsome mirth
The burdened muse above the dust of earth,
To stamp with jests the heavy ore of thought,
To give a day, with proud remembrance fraught,
The vital pathos of that Holmes-spun art
Which knew so well to reach the common heart.
Alas! for me, for you, that fatal hour!
Gone is the master! Ah! not mine the power
To gild with jests, that almost win a tear,
The thronging memories that are with us here.

The Birth of Pain! Let centuries roll away;
Come back with me to nature's primal day.
What mighty forces pledged the dust to life!
What awful will decreed its silent strife!
Till, through vast ages, rose on hill and plain
Life's saddest voice, the birthright wail of pain.
The keener sense, and ever-growing mind,
Served but to add a torment twice refined,
As life, more tender as it grew more sweet,
The cruel links of sorrow found complete,
When yearning love to conscious pity grown
Felt the mad pain-thrills, that were not its own.

What will implacable, beyond our ken,
Set this stern fiat for the tribes of men?
This, none shall 'scape, who share our human fates:
One stern democracy of anguish waits
By poor men's cots—within the rich man's gates.
What purpose hath it? Nay, thy quest is vain;
Earth hath no answer: If the baffled brain
Cries, 'tis to warn, to punish—Ah, refrain!
When writhes the child, beneath the surgeon's hand,
What soul shall hope that pain to understand?
Lo! Science falters o'er the hopeless task,
And Love and Faith in vain an answer ask,
When thrilling nerves demand what good is wrought
Where torture clogs the very source of thought.

* * * * * *

Whatever triumphs still shall hold the mind,
Whatever gifts shall yet enrich mankind,
Ah! here, no hour shall strike through all the years,
No hour as sweet, as when hope, doubt, and fears,
'Mid deepening stillness, watched one eager brain,
With God-like will, decree the Death of Pain.

How did we thank him? Ah! no joy-bells rang,
No pæans greeted, and no poet sang,
No cannon thundered, from the guarded strand
This mighty victory to a grateful land!
We took the gift, so humbly, simply given,
And coldly selfish—left our debt to Heaven.
How shall we thank him? Hush! A gladder hour
Has struck for him; a wiser, juster power
Shall know full well how fitly to reward
The generous soul, that found the world so hard.

* * * * * *

A solemn hour for such as gravely pause
To note the process of creation's laws!
Ah, sure, He, whose dark, unfathomed Mind
With prescient thought, the scheme of life designed,
Who bade His highest creature slowly rise,
Spurred by sad needs, and lured by many a prize,
Saw, with a God's pure joy, His ripening plan,
His highest mercy brought by man to man.

The last speaker was Lord Playfair of London.

"I believe I am the only person called upon to speak," he said, "who was not informed of that fact in advance, and therefore, as I am unprepared, what I have to say will be very brief. I feel a great pleasure at being here, because I have taken a deep interest in each step in the discovery of anesthesia.

"I remember well how we welcomed the news from America. One of my most intimate friends was Sir James Simpson, who was not a rival, but a colleague.

"Let me say here that there is no jealousy in regard to this discovery. It is undoubtedly due to the United States.

"The man entitled to the right of discovery is the man who realizes it to the world. The credit of this discovery is undoubtedly due to Morton in the first instance. Sir Humphry Davy made some experiments in this line, but he never realized the importance of ether."

SOCIETY PROCEEDINGS.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Ninth Annual Meeting, held in Richmond, Va., September 22, 23, and 24, 1896.

(Continued.)

A. H. CORDIER, M.D., of Kansas City, Mo., read a paper on

MOVABLE KIDNEY; LOCAL AND REMOTE RESULTS.

He drew the following deductions: (1) A movable kidney often produces a dilatation of the stomach, with all

the accompanying symptoms of a disease of that organ. (2) It is a fruitful source of gall-stones, because of the pedicle producing a partial obstruction of the common duct. (3) The bending of the ureter often gives rise to a hydronephrosis. This, in turn, is sometimes converted into a pyonephrosis. (4) It may produce death by causing a torsion of the vessels and ureter. (5) By dragging on the abdominal aorta and kinking the vena cava a condition simulating an aneurism of these vessels may be produced. (6) Pain which is referred to the region of distribution of the spinal nerves is often induced by a movable kidney's disturbance of the abdominal brain. (7) A general nerve-exhaustion (neurasthenia) is often induced by the interference of this condition with digestion, assimilation, and elimination. (8) Nephrorrhaphy is a safe and effective surgical procedure. (9) All cases of movable kidney, if accompanied by symptoms pointing to the kidney as their source, should be operated on. (10) In summing up the local and remote results of this now often recognized condition, the author thinks the correctness of the deductions has been frequently demonstrated by the disappearance of each and every symptom after a restoration and retention of the kidney in its normal position. (11) The physical examination is the only trustworthy guide in making a diagnosis of movable kidney.

Hugh M. Taylor, M.D., of Richmond, Va., read a paper on

THE LIMITS OF NEPHRORRHAPHY.

He favors the classification of nephroptosis under three clinical heads: (1) Patients who have displaced kidney, do not know it and suffer no inconvenience whatever from it. This type he thinks represents by far the largest class. (2) Patients with displaced kidney, who may or may not know it, who suffer from gastroënteric discomfort, and perhaps, a long train of vague neurotic disturbances. In this type he thinks we find the largest class calling for operative interference. (3) Patients with movable kidney who are subjects of occasional, or frequent mild or severe attacks of renal crisis. This last-mentioned is, he thinks, the least frequent type met with, but the urgency of the symptoms more frequently demands operative interference.

Nephrorrhaphy, for the relief of gastroënteric disorder, is limited by our ability to tell to what extent the disorder is due to renal ptosis *per se*, or to enteroptosis, or to some one of the many well-known etiological factors of gastroënteric disorders. Nephrorrhaphy, for the relief of the condition of Deitl's or renal crisis, must be limited by one's success in differentiating between this condition and that of gall-tract, appendicular, and kidney colic, due to nephrolithiasis. He accepted as logically sustained the conclusion that the Deitl's or renal crisis is due to a kink or twist of the ureter, with retained urine in the ureter, and pelvis of the kidney. Apart from the violent paroxysms of pain (the renal crisis), the tendency of ureteral twist and urinary obstruction to induce hydronephrosis, and, in exceptional instances, pyonephrosis, rendered operative interference more imperative in this class of cases.

His protest was not against nephrorrhaphy, but only its abuse. He conceded the value of operative interference in many selected cases, but deprecated the tendency toward operative interference merely because the kidney is movable.

Dr. George Ben Johnson of Richmond, Va., had operated for movable kidney in three cases with most gratifying results.

Dr. L. H. Dunning laid great stress upon the importance of differentiating between floating and movable kidney, the former being always congenital, the latter acquired to a greater or less extent. The two principal causes of the partially fixed condition of the kidney were its position behind the peritoneum, and the fact that it had an envelope of cellulo-adipose tissue. The perinephritic cellulo-adipose tissue was composed of two parts, one fixed, the other movable. The normal kidney had a range of motion of from one-half to three-quarters of an inch in its fatty envelope.

Dr. Thos. B. Easemann of Indianapolis reported the case of a woman, twenty-five years of age, who came to him with the symptoms of appendicitis. She also had considerable albumin in the urine. Operation showed that the appendix was firmly adherent to the kidney. It required considerable force to liberate it. As soon as liberated the kidney bounded back into place as though it were rubber. The appendix was removed, the albumin in the urine ceased, and the woman made an uneventful recovery.

Dr. James McFadden Gaston of Atlanta directed attention to the possibility of movable kidney being mistaken for enlarged gall-bladder. The gall-bladder is capable of being pushed back into the lumbar region, and carried around in front in just the same manner as a floating kidney.

Dr. J. S. Stone of Washington, D. C., related a case of a woman who, after the operation of nephrorrhaphy had been performed, gained twenty-five pounds in flesh. In many instances this procedure brought color back to the cheeks of patients and made them feel well.

Dr. Joseph Price said that his experience had been somewhat limited in operating for movable kidney. The improvement in the condition of patients so operated upon was rapid, but there was such a thing as operating too much in these cases.

Dr. J. Henry Carstens of Detroit said, the line should be drawn between movable and floating kidney. The trouble which arose from floating kidney consisted of a twisting of the ureter and consequent obstruction.

W. E. B. Davis, M.D., of Birmingham, Ala., read a paper on

TREATMENT OF PERIUTERINE SEPTIC DISEASES.

Only recently has the extremely radical procedure of hysterectomy been practised in this country for septic diseases of the internal genitals. A wave, which had its origin in Paris at the hands of Péan, aided by Richelot, Segond, Jacobs, and others, reached our shores three years ago, and has found a considerable following among our leading operators. The claim is made that there is no use in leaving the uterus after the removal of the ap-

pendages; in every operation for septic diseases of the female generative organs, which demands the removal of the tubes and ovaries, hysterectomy should also be performed, unless there are plain contra-indications forbidding it. It should be the aim of the surgeon to preserve everything consistent with thorough surgical work, and not to sacrifice important organs because it can be done with only a small mortality. The sexual life of the woman is very much better preserved by leaving the uterus, and the mental effect is also much better. A slow convalescence, or even a second operation, is preferable to its removal unless very much diseased. As stated by Dr. Davis at the last meeting of the American Medical Association, he could not agree with Dr. Sutton and others that pus in the tubes was due to gonorrhea in seventy-five per cent. of cases. He thought that puerperal infection was the cause of more than fifty per cent. Tubercular infection was rarely the cause, and was not so important as had been claimed. However, the importance attached to gonorrhea was against the argument for the removal of the uterus, as the infection from this source was not deep and could be removed with the curette. Because some patients were not completely cured by the removal of the appendage, was no argument for hysterectomy in every case where the bilateral operation was required; for nearly all these could be relieved by a thorough curettage.

Vaginal incision for the drainage of pus in the pelvis, not confined to the tubes, was a most valuable method of treatment in a well-recognized class of cases, and had been practised for a long time with gratifying results. A large number of these cases required no further surgery. More recently large pus-tubes and ovarian abscesses had been incised and drained through the vagina with permanent recoveries in a large proportion of cases. The uterus should always be curetted at the same time. These were the very cases where the vaginal operation and hysterectomy had been recommended so highly by the French surgeons. Yet a considerable percentage of these cases could be relieved by vaginal incision and drainage. The object of the surgeon should be, not so much toward still further reducing the death-rate from the operation, but to relieve the cases and preserve, as far as possible, organs which had so much to do with the woman's health and happiness.

L. H. DUNNING, M.D., of Indianapolis, read a paper entitled

SHALL HYSTERECTOMY BE PERFORMED IN INFLAMMATORY DISEASES OF THE PELVIC ORGANS?

The author discussed only diffuse pelvic inflammation.

He recognized the utility of hysterectomy in a small percentage of cases of bilateral suppuration of the tubes and ovaries in which the uterus is distinctly septic, and in cases of septic uteri, which cannot be cured by other means after bilateral salpingo-oöphorectomy.

He opposes hysterectomy as a rule.

E. F. FISH, M.D., of Milwaukee, Wis., read a paper entitled

SHALL THE UTERUS BE LEFT IN SITU IN EXCISION OF THE ADNEXA?

He argued against all operations which leave a degenerated uterus, such as Hegar's, Tait's, Martin's, and Robinson's, except under extreme conditions, and concludes thus: (1) That whenever it becomes necessary to excise the uterine adnexa, if the uterus is sound, leave it. (2) Whenever we excise the tube and ovaries, and the uterus, though in a pathological condition, in our judgment will yield to treatment, leave it. (3) Whenever it is necessary to do an abdominal hystero-salpingo-oöphorectomy and the cervix is healthy, do a supravaginal amputation, as this leaves the vaginal vault intact. (4) Whenever it is necessary to do a supravaginal amputation, suspend the cervix to the stumps of the broad ligaments, or anchor it to the abdominal wall, to prevent prolapsus vaginæ. (Baldy.) (5) Whenever it is necessary to do a general ablation, and the cervix uteri is unsound, take the entire organ because of the danger of carcinoma. (6) Whenever a subserous or insterstitial myoma can be removed without too great damage to the uterus, do a myomectomy and leave the organ. (7) Whenever we excise the appendages and leave the uterus, ventral fixation is not an unsurgical operative conclusion. The author's reasons for leaving the uterus were: (*a*) That it helps to maintain the woman's sexual integrity. (*b*) It relieves the patient of much mental strain, and is a prophylactic measure to neurasthenia, melancholia, and insanity. (*c*) It tends to maintain the family ties unstrained. (*d*) It obviates the possibility of vaginal hernia, cystocele, and protocele, and delays vaginal atrophy, and last of all, it holds up and prevents shortening of the vagina.

A spirited discussion followed the reading of the above three papers.

J. W. LONG, M.D., of Richmond, Va., contributed a paper entitled

DYNAMIC ILEUS.

The following is a report of one of Dr. Long's cases: Mrs. C., was brought to him on May 27, 1896. She is twenty-one years old, married three years, but never pregnant. It was with great difficulty that she could be induced to have any local treatment or even take her medicines. Early in the April of this year, the patient had malaria, followed by delayed menstruation, pelveo-abdominal pain, and obstinate constipation. The malaria and menstrual disturbance yielded promptly to treatment, but the abdominal pain continued, and gradually the ileus symptoms became more and more pronounced. After exhausting every other measure to move the bowels, the patient was given chloroform, and by means of a Rickett's tube he succeeded in washing away a quantity of fecal matter. There was no improvement, and a marked degree of tympany supervened. When she was brought to the hospital, there had been no movement of the bowels for four weeks, fecal matter being washed away with the colon-tube while the patient was anesthetized. The history justified the diagnosis of intestinal obstruction, while the urgent symptoms demanded an immediate operation. The abdomen was opened by a median incision. No mechanical obstruction could be found, although a careful search was made along the whole

length of the intestine. The bowel was moderately distended with gas and congested. At three points, two in the ileum and one in the sigmoid flexure, the canal was constricted sufficiently to constitute obstruction. In the ileum, one of the constrictors was about fifteen inches from its lower end and six inches long, the other was near the jejunum and about four inches long. The lumen was not entirely closed at either point, but was greatly reduced, being less than half the normal size, while the diameter of the remaining portions of the bowel was increased on account of the distention with gas. No peristalsis was observed, but the contracted portions could be dilated by "milking" the intestinal contents along. In the sigmoid, the limitations of the contracted portion were not so sharply defined, but the lesion was just as evident. The walls were thickened and the caliber much diminished. Incidentally, a small ovarian cyst on the right side was discovered and removed. As the intestine had been handled a good deal, the abdomen was flushed with normal salt solution. The incision was closed with two tiers of sutures, silk for the peritoneum, and interrupted silver wire for the remaining layers. The recovery ere most satisfactory in every way. The bowels responded to the usual laxatives and enemas on the second day, and from the first to last there was not a hitch in her convalescence. The patient left the hospital in four weeks, and three weeks thereafter took a trip to Alabama. There could be discovered no evidence of lead or ptomain poisoning.

B. M. Hypes, M.D., of St. Louis, read a paper on

SPONTANEOUS RUPTURE OF UTERUS DURING LABOR AT TERM, WITH SPECIMEN.

Mrs. O., aged thirty-one, of German parentage, general health good, previous to birth of first child. No history of any constitutional disease. After the birth of her first child, which lived but a few minutes, she suffered for six weeks from a severe case of metro-peritonitis. For the next few years she was a sufferer from general debility, impaired digestion, and a "sore spot" in the hypogastrium. Four years from the birth of her first child she again became pregnant. During gestation, her general health was much improved. She exhibited no functional disturbances; her only complaint was the sore spot over the fundus of the uterus and to the right of the median line. Labor pains began September 16, 1895, at 10 P.M., at full term. The family physician was called; found labor in progress, vertex presentation, with normal condition of mother and child. The pains were slight and progress slow. At 2 A.M., September 17th, he gave a dose of morphin and went home. At 9 A.M., upon his return, he found the patient comfortable, with occasional slight labor pains. He left the house with injunction to call him when signs of labor became pronounced. Patient remained quiet during the day. Suddenly, at 3 P.M., she was seized with violent vomiting, and the usual symptoms of abdominal shock. The family physician was at once sent for, and upon his arrival at 4 P.M. found her in complete collapse, with convulsive seizures. The patient had suffered spontaneous rupture of the uterus. He at once dispatched for surgical aid, but by the time the surgeon, Dr. Meisenbach, arrived, the patient was moribund. Laparotomy was hastily performed, and the child, which had escaped entirely into the abdominal cavity, was extracted from a mass of blood and amniotic fluid. It had ceased to live, and continued efforts at resuscitation failed to cause it to breathe. The child was fully developed, male, weighed six pounds, and was eighteen inches long. The uterus, when removed from the body, presented the following condition: A rupture through fundus, superiorly, extending half an inch from the entrance of one tube to an equal distance from the entrance of the other; the walls, at place of rupture, were comparatively thin. Placenta located at middle third of uterus, anteriorly, and to the right, where the walls were much thickened. Vaginal portion of the cervix almost obliterated as at term, and dilated for the ready admission of two fingers. The lower zone of the uterus exhibited no thinning or formation of Bandl's contraction-ring; no disease of tubes, ovaries, or placenta. A microscopical examination was made soon after rupture, and revealed fatty degeneration of tissue at point of rupture. The points of unusual interest in the case are the cause of the rupture, and its location at the fundus uteri.

Edwin Ricketts, M.D., of Cincinnati, O., read a paper entitled

PORRO'S OPERATION AT OR NEAR THE FIFTH MONTH FOR SMALL FIBROID OF CERVIX, ACCOMPANIED BY HYDRAMNIOS AND TOTAL RETENTION OF URINE.

The author reported the following case: Mrs. M., white, aged twenty-six, of short stature, mother of two children of six and three years of age, with an abortion at eight weeks early in 1895, no specific history. From January 10, 1896, she had no desire to urinate, nor could she void a drop of urine without the aid of the catheter. On February 23, 1896, she had severe labor pains lasting thirty-six hours, and accompanied by slight hemorrhage, the right portion of the cervix being soft and the left hard, which condition was also present at the time of operation. During April and until May 22d, the date of operation, she was very tender over the lower part of the abdomen, and at times had a temperature above 100°, with a pulse running from 90 to 100. On May 22d her abdomen was found to be larger than it should be at full term, which was due to the hydramnios present. There was no difficulty in moving the fetus freely in the abdominal cavity, so thin was the uterine wall. It was considered unwise to delay surgical interference, and a Porro operation was therefore performed under as strict asepsis as the circumstances would permit. After the abdomen was opened, Dr. Ricketts passed his hand down into the pelvis, breaking up the pelvic adhesions. Upon the delivery of the fundus of the impregnated uterus through the abdominal incision, a rubber ligature was thrown around it, low down and tight enough to control any hemorrhage which might occur. The fluid which escaped, upon opening the uterus, surpassed in amount any he had seen delivered per viam naturalem. After carefully sponging the parts, the wire was tightly adjusted below the rubber ligature by means of the Koeberle clamp, and the rubber ligature then removed. After the delivery of the placenta

the fundus was amputated, leaving the ovaries and tubes intact. The abdominal wound was closed with silkworm-gut sutures, without stitching any tissue to the stump below the wire. No drainage-tube was used. The extra-peritoneal part of the stump was dressed with gauze, moistened in glycerin and tincture of iron, the stump being held up by the double-hooded pin of Tait. The placenta and fetus were small for a gestation of nearly five months, and the cord was tied in almost a hard knot —harder than any he had seen. The fetus had marked cyanosis and gasped but once. Recovery of the mother was satisfactory.

H. W. LONGYEAR, M.D., of Detroit read a paper on

TREATMENT OF PUERPERAL INFECTION.

He spoke of the treatment of infection from abortion and from childbirth at full term, and presented an instrument for use in removing the remains of secundines from the uterus, designed by him. He also exhibited a self-retaining drainage-tube of his own invention. He reported two cases of puerperal infection treated successfully by the use of diphtheria antitoxin serum. He condemned the performing of hysterectomy for puerperal septicemia, except in very exceptional cases.

WM. G. MYERS, M.D., of Fort Wayne, Ind., read a paper entitled

ATRESIA WITH RETENTION OF THE MENSES: TREATMENT.

He reported two cases of atresia, one with absence of the vagina and uterus, and the other with retained menstrual fluid. The last was operated upon successfully. He believes that in the case of atresia of the vagina, with retention of menstrual fluid in the uterus, an operation ought to be completed at one sitting, adopting the direct method.

JOSEPH PRICE, M.D., of Philadelphia, delivered the President's address on

PRINCIPLES AND PROGRESS IN GYNECOLOGY.

GEORGE H. ROHE, M.D., of Sykesville, Md., read a paper on

SOME CAUSES OF INSANITY IN WOMEN.

At the period of puberty menstrual derangements are not infrequently causative of mental disturbances, which do not yield until the menstruation becomes normal. In the puerperium, insanity is dependent upon septic absorption, or the consequences of other morbid conditions of the reproductive organs. Lactational insanity may be due to physical exhaustion, but in some cases pathological conditions of the genitals or of the breast seem to have an etiological relation. At the menopause the disturbances of nutrition, associated with the arrest of menstruation, often produce insanity, and in many of these cases there will also be found abnormal alterations of the reproductive organs. The insanities following gynecological operations are either due to septic conditions, or are merely due to the rapidly induced menopause. Their frequency has been much exaggerated.

WALTER P. MANTON, M.D., of Detroit, Mich., read a paper on

THE RELATION OF VISCERAL DISORDERS TO THE DELUSIONS OF THE INSANE.

That the delusions of the insane are often an expression of somatic peripheral irritation has long been recognized, but observation leads him to believe that the importance of these mental manifestations, as indices of bodily suffering, was frequently ignored as a mere phase of the brain-disorders, especially in the instance of supposed fancied visceral disturbances.

He reported interesting cases. In each of the patients the delusions referred chiefly to the abdomen, and in each an abnormal condition of some of the viscera was found, but a condition in which the early intervention of surgery would have afforded great, if not permanent, relief to the sufferings of patients. Laparotomy, in properly selected cases of the insane, in whom visceral delusions are a pronounced and constant feature of the mental disorder, was not only justifiable in his opinion, but urgently demanded in the interest of the patient.

DAVID T. GILLIAN, M.D., of Columbus, O., read a paper entitled.

OÖPHORECTOMY FOR THE INSANITY AND EPILEPSY OF THE FEMALE: A PLEA FOR ITS MORE GENERAL ADOPTION.

He showed that oöphorectomy was a logical and legitimate operation for the epilepsy and insanity of the female. Insanity is hereditary, as is also epilepsy. They constitute the greatest curse to humanity. He would limit the operation to those in whom the malady appears in some way to be connected with or dependent on sexual disturbance. He would go further and include all who were willing to undergo the operation to save themselves and their offspring from the miseries which awaited them.

J. F. BALDWIN, M.D., of Columbus, O., read a paper on

TREATMENT OF THE STUMP TO PREVENT ADHESIONS.

He estimated that about one per cent. of all cases operated upon die from intestinal obstruction, the result of adhesions to the stump. To diminish as much as possible the danger of adhesions, he recommended the careful closing in of stumps by a peritoneal flap, and described the method of securing this flap. In cases where the pedicle is, after a simple ovariotomy, not too large, he recommended that the pedicle be so ligated that the ends of the ligature were on the anterior face of the pedicle; that the ends of the ligature be then carried across the face of the stump, down and through the broad ligament, transfixing the ligament from behind forward. The ligatures should be passed through, about half an inch apart. As the ends are drawn through and tightened, the raw end of the stump is rolled down and under the broad ligament, so as to be entirely protected. He used this method in a large number of cases, and with entirely satisfactory results.

THOMAS E. MCARDLE, M.D., of Washington, D. C., read a paper on

ABDOMINAL SECTION FOR TUBERCULAR DISEASE.

The treatment of tuberculosis of the vulva, vagina, and

cervix, did not come within the scope of the paper. The destruction of the tuberculous focus by fluid or solid caustics had been advocated by some surgeons, and if these means were not satisfactory, extirpation of the part was recommended. We had a very efficient means for the removal of the tubercular ulcers of the vagina and vulva in the application of the tincture of iodin. They rapidly disappeared under its use. In case of failure, however, excision could be practised. When the cervix is involved, and not the body of the uterus, the method of treatment advised for the vulva and vagina should be given a fair trial, but if they prove ineffectual, no time should be lost in amputating the cervix. When the endometrium is involved, there is a diversity of opinion as to the best method of procedure. It has been recommended first to curette the organ and remove all evidence of disease. The iodoform suppositories are introduced into the uterus. If there should be a recurrence of the trouble, removal of the organ is advised. Having once ascertained the existence of tubercular disease in the uterus, it is our duty to look for a similar condition in the tubes and ovaries, and, if found, it behooves us to waste no time in curetting the uterus and treating it with iodoform, but to proceed at once to the performance of an abdominal section for the removal of the uterus, tubes, and ovaries. This heroic method of treatment is advocated in primary disease of these organs. In cases complicated with tubercular peritonitis, there would be no special danger in removing the tubes and ovaries. We all know how many cases of that disease have been cured by section and drainage. We could then curette and treat the body of the uterus.

Charles A. L. Reed, M.D., of Cincinnati, O., read a paper on

MELANO-SARCOMA OF THE FEMALE URETHRA; URETHRECTOMY; RECOVERY.

Mary E. Y., aged sixty-four, single, was brought to his private hospital December 3, 1895. The patient had had no previous serious illness. There was no history of tuberculosis or syphilis in the family. The virginal condition of the genitalia precluded the supposition of venereal infection of any character. Her general health was good, although there was some emaciation about the neck and breasts, the latter of which were flabby—changes no doubt incident to age. Careful examination revealed no diseased conditions about either the lungs or heart. Careful palpation and percussion of the abdomen yielded negative results. About eight months previously—*i.e.*, in April, 1895—she began to notice some pain accompanied with blood on micturition. This was shortly followed by a more or less constant pinkish discharge from the genital fissure. The self-examination which followed revealed a tumor at the meatus urethræ. This tumor continued to increase in both size and hemorrhagic tendency until she was prompted to consult Dr. Morris, who curetted the neoplasm thoroughly, and treated it with styptics. When the patient came under Dr. Reed's care, he found a black lobulated and eroded mass, about three centimeters in diameter, separating the labia majora. The orifice of the urethra was in the very center of this mass. A careful vaginal examination was made at the time, as the virginal structures, present in their integrity, rendered such an operation very painful. Operation was done the next day, December 4th. The small blade of a Jones' speculum was introduced; the patient being in the Simon's posture, the urethra was by this means exposed in its entire length. A longitudinal incision was made through the mucous membrane along the dorsum of the urethra, from a point where the presenting part of the mass was eroded to the base of the bladder. Another incision through the mucous membrane was made at right angles to the foregoing at a point far enough above the eroded mass to insure healthy tissue. The mucous membrane was then dissected back in two lateral flaps, and the urethra was enucleated. The urethra was found to be distinctly conical in shape, the base of the cone being at the meatus, the apex at the bladder. Care was taken to dissect out the canal to a point manifestly above the zone of malignant involvement. When this point was reached, but a slight distance from the bladder, the canal, with the neoplastic walls, was excised. The cut margin of the cystic segment of the canal was seized at various points in its circumference by Kocher's forceps, brought down by gentle traction, and fixed by interrupted sutures of silkworm-gut to the vaginal mucous membrane. A self-retaining catheter was inserted, and the patient was put to bed. The sutures were removed on the eighth day. The catheter was dispensed with on the twelfth day. The patient sat up on the fourteenth day, when she found that she could retain her urine and void it at will. She was dismissed December 21st, entirely healed. She remained in good health until the 1st of July following—seven months—when she again summoned Dr. Morris because of some gastric symptoms. He found her suffering from persistent vomiting, and with a large mass in the epigastrium. This mass rapidly increased in size until it occupied all the area between the navel and the breast-bone, its nodular characteristics becoming more and more pronounced. She died of exhaustion July 14, 1896, having had no recurrence whatever of the urethral trouble. No autopsy was permitted.

J. B. Murphy, M.D., of Chicago, addressed the Association on

THE SUTURE OF LARGE VESSELS INJURED IN OPERATIONS.

His own researches and operative work lead him to believe that, where a large vessel is injured in an operation by a transverse division, not exceeding two-thirds of its circumference, the surgeon can resort to immediate suture without resection, and, if the field of operation be aseptic, can feel more certain that he will have union of the vessel and continuation of the current than he could where he sutures the intestine as for the resection of the bowel. He believes from his observations that the chances are better with the suture. The importance of this concerned surgeons more in the treatment of aneurisms. Coming to the question of stab- and bullet-wounds of the extremities, he said there was a great field for improvement in our past operative work. Formerly, we ligated vessels, and when this was done the inevitable result was death of the limb. He believes that now such limbs can

be uniformly saved, particularly in the aseptic cases. With his present method of suturing large vessels, he is not afraid to suture any vessel in the body, feeling confident that adhesion or union will take place.

W. G. Macdonald, M.D., of Albany, N. Y., read a paper on

CONTUSIONS OF THE ABDOMEN.

Contusions of the abdomen are always grave injuries. The question of surgical intervention, although much discussed, cannot be regarded as satisfactorily settled. Seven cases of traumatic rupture of the stomach and small intestine are reported. Two operations were undertaken, one recovery, one death the eighth day after operation from second rupture. All the inoperative cases died. Reference is made to the general absence of evidence of contusions in the abdominal walls, when serious visceral injury has occurred. Very slight causes, particularly if the intestinal canal is distended with fluids, may produce intestinal rupture. The early symptoms of intestinal laceration are not always distinctive. An analysis of two hundred cases of intestinal laceration, as associated with abdominal contusion, was made with a view to determine the symptoms. The following topics are considered the important ones: History of the nature of the injury, shock or collapse, pain, vomiting, pulse, temperature, and physical signs. That careful investigation of a given case will usually show sufficient symptoms to make an early exploratory abdominal section imperative.

The following officers were elected: President, Dr. James F. W. Ross, Toronto, Canada; secretary, Dr. Wm. Warren Potter, Buffalo, N. Y.; treasurer, Dr. X. O. Worder, Pittsburg, Pa.

The next meeting will be at Niagara Falls, N. Y., August 24, 25, and 26, 1897.

REVIEWS.

Diagnosis and Treatment of Diseases of the Rectum: Being a practical treatise on Fistula, Piles, Fissure and Painful Ulcer, Procidentia, Polypus, Stricture, Cancer, etc. By William Allingham, F.R.C.S., Eng., and Herbert W. Allingham, F.R.C.S., Eng. Sixth edition. William Wood & Co., 1896.

The name Allingham has been so intimately associated and for so long a time with the treatment of diseased conditions of the rectum, that an enlarged and improved edition of this work is a welcome contribution to the subject. The subjects treated in the book are attracting constantly increasing interest and more definite and scientific attention from year to year. As is truly said in the introduction, a majority of these affections are very amenable to proper treatment. The amount of relief afforded sometimes by a most simple treatment or surgical procedure is most surprising and gratifying. The importance of administering an anesthetic for the purpose of thorough and careful diagnosis is wisely insisted upon.

The various operations for hemorrhoids are fairly and fully described, but the authors reassert the opinion that the ligature is the best and safest operation for the great majority of cases. Whitehead's operation for hemorrhoids is criticised, and the assertion is made without hesitation that, though theoretically it is perfect, yet in practise it is unnecessary, and one of the worst operations for piles. The experience of many skilful surgeons in this country would hardly corroborate this opinion. Indeed, with proper modifications of the original procedure, as described by Whitehead, there is no reason why it may not be as perfect in practise as it is in theory. Even in this, the sixth edition, there is little attempt made to improve upon the early style in which it was written, and the reports of cases that are presented read vastly like advertisements of patent medicines in the daily papers. Some valuable recent contributions to the study of these diseases are not mentioned. No reference whatever is made to Howard Kelly's method of examining and treating the rectum.

A Manual of Clinical Diagnosis by Microscopical and Chemical Methods. For Students, Hospital Physicians, and Practitioners. By Charles E. Simon, M.D., Late Assistant Resident Physician Johns Hopkins Hospital, Baltimore. In one very handsome octavo volume of 504 pages, with 132 engravings and 10 full-page colored plates. Cloth, $3.50. Lea Brothers & Co., Philadelphia and New York. 1896.

The practice of medicine nowadays is a true science and art. "Diagnosis" is the most important subject of medical knowledge. Chemistry and bacteriology have recently given us aid of incalculable value in establishing a diagnosis with scientific precision. Those fruits, however, should not be left for a few experts alone, but should become the common property of the entire medical profession. With this aim in view, Simon has written this excellent work, which gives, in clear language and concise words, all the new methods of bacteriological, as well as chemical, investigations necessary for the practitioner. The chapters on "blood," "sputum," "gastric contents" and "urine" are treated in a masterful way, which can hardly be excelled. Many of the methods described are original. The illustrations, many of them in colors, are beautifully executed and of incalculable assistance to the practical worker. The book possesses the attractive features of freshness, clearness, and originality—a guaranty of wide circulation and great usefulness.

Ptomains, Leucomains, Toxins, and Antitoxins; or the Chemical Factors in the Causation of Disease. By Victor C. Vaughan, Ph.D., M.D., Professor of Hygiene and Physiological Chemistry, and Frederick G. Novy, M.D., Junior Professor of Hygiene and Physiological Chemistry in the University of Michigan. New (3d) edition. In one 12mo. volume of 603 pages. Cloth, $3.00. Philadelphia: Lea Brothers & Co. 1896.

The first edition of this book appeared in 1888 and the present is the second edition since that time—evidence that the work has been favorably received. And so it

should be, for the subject-matter treated is of the utmost importance to those interested in the intimate nature of the processes of infection. The "mechanical interference" theory of infection was never a satisfactory one, but for a time was practically the only one. During the past few years, as a result of laboratory methods of investigation, we have come to look more and more upon the clinical and pathological manifestations of infectious processes as the outgrowth of various kinds of intoxications, or, perhaps better, as in most cases the result of the direct action upon the tissues of poisons, either contained in the protoplasmic bodies of bacteria themselves, or eliminated by the bacteria in the course of their growth. In other words, infection now seems to be a chemical phenomenon. Still another important advance has been made in the means of combating these processes. It has been found that by particular manipulations animals may be rendered tolerant to the poisons of infection and that in some cases such animals contain in their circulating fluids antidotes to the poisons to which they have acquired a tolerance—in other words their body-fluids, especially the serum of their blood, are "antitoxic." This latter observation has already proven to be of the greatest therapeutic importance in certain instances, and as investigations are continued in this direction the field of usefulness will undoubtedly be broadened. To all interested in this subject, and it goes without saying that every student of medicine should be included in this category, the book of Vaughan and Novy will be of the greatest assistance. It presents in a concise way the latest views on the subject, bringing together the more important studies on which the opinions of to-day have been formulated. The chapter (Chap. II.) on the history of the development of our knowledge of bacterial poisons is especially interesting; as is also the chapter (Chap. V.) on the relation of bacterial poisons to infectious diseases. We cannot agree with the authors (Chap. VIII., p. 234) that "exposure to a given disease for successive generations is one of the factors in the evolution of natural immunity," for we do not believe that natural immunity has evolved, but rather that it is a property inherent to the idioplasm of the species endowed with it. There is no evidence of its having been acquired. To use the author's own illustration, p. 232, the chick that is immune to anthrax is in this particular just like every other chick, the world over; its immunity to this disease is a species-characteristic that is natural to it, and has probably always been so; at least there is no proof to the contrary. The community of human beings that for successive generations has been exposed to some particular form of disease and has finally become less susceptible, and, indeed, as in a few individual instances, totally immune, has *acquired* a trait that is *not* a natural characteristic of the *species*, for the balance of the species still retains its normal susceptibility to that malady. We cannot say that man is *naturally* immune to syphilis or yellow fever because we find in certain localities individuals who, because of the constant exposure of themselves and their progenitors to these troubles, have acquired a condition of increased resistance to them. To say that a person is naturally immune to a disease, because of the increased resistance afforded to him by a single non-fatal attack, would manifestly be absurd; and to admit that natural immunity, in the strict sense in which the term is understood by the reviewers, represents often all the inheritance of an induced peculiarity, is to admit in general the possibility of the hereditary transmission of acquired traits, an assumption that, according to Weismann, "has often been made but never yet proved."

To the student of medical jurisprudence the chapter (Chapt. XI.) on the importance of bacterial products to the toxicologist, will prove profitable reading.

A useful feature of the work is the full bibliography, which appears in the form of an appendix.

The Ready-Reference Handbook of Diseases of the Skin. By George Thomas Jackson, M.D., Professor of Dermatology, Woman's Medical College of the New York Infirmary and in the University of Vermont; Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons, New York. New (2d) edition. In one 12mo. volume of 589 pages, with 69 illustrations and a colored plate. Cloth, $2.75. Philadelphia: Lea Brothers & Co. 1896.

The appearance of a second edition, is, in a measure, a refutation of any adverse criticism that may have been accorded the original. When, however, the author and publisher combine in pointing out the superiority of the rewritten work, one must judge that room for improvement had existed. In dermatology, however, changes of belief are frequent, and new names, if not new diseases, are constantly arising. The author is therefore justifiable in making alterations and improvements. In the work now presented these are noticeable at frequent intervals through the text, and also in the matter of illustration, of which some twenty new ones have been added. In the additions of new subjects are to be noted chapters on actinomycosis, angioma serpiginosum, Baelzer's disease, dermatitis repens, multiple, benign, cystic epithelioma, porokeratosis, and a number of others.

The text, as a whole, has been considerably increased.

In a "ready-reference" handbook the alphabetical arrangement has advantages over many of the older classifications and lends no element of confusion to the student in a subject which is generally supposed to be confusing enough at best. Synonyms being given, as the names occur in turn, adds a glossary-like element, which must often be of decided value. Tables of differential diagnosis scattered here and there offer a quick way of getting at points of doubt. In an appendix a long list of formulæ are given. The size, general appearance, and usefulness of the book have all been increased and Dr. Jackson is to be correspondingly congratulated.

Cheerful Philosophy for Thoughtful Invalids. By William Horatio Clarke. E. T. Clarke & Co., publishers, Reading, Mass.

This little volume of forty-one pages, as its name indicates, is addressed to those afflicted ones who have been compelled to give up the activities of life and be confined

to the narrow limits of the sickroom. Its purpose is to fill the hearts of these sufferers with courage and make them feel that their lives still may be useful not only in development of their own characters, but in influencing and blessing other lives that are brought into contact with theirs. It certainly shows that there is a bright side to even an invalid's life, and no doubt will help many such to take heart.

BRAITHWAITE'S RETROSPECT OF MEDICINE. January to June, 1896. Simpkin & Co. G. P. Putnam's Sons, American publishers.

THIS volume appears in its usual form, and covers quite fully the whole range of medicine and surgery. Considerable space is given to the antitoxin treatment of diphtheria and serumtherapy generally.

USES OF SUFFERING. By G. W. H. KEMPER, Member of the Delaware County (Ind.) Medical Society. 1896.

THIS little book of fifty-six pages, bound in cardboard cover, consists of a number of short essays, which the preface describes as a "plea for the goodness of God as manifested in disease and suffering." The publication is made at the request of a number of friends—evidently personal and admiring friends. The reader will not question the prefatory statement that they were written amid inconvenient and distracting cares, and "always within earshot of some sufferer."

A TEXT-BOOK UPON THE PATHOGENIC BACTERIA FOR STUDENTS OF MEDICINE AND PHYSICIANS. By JOSEPH MCFARLAND, M.D. Cloth, 359 pages, with 113 illustrations. Philadelphia: W. B. Saunders, 1896.

THE professed purpose of this book is to present to the student and medical body a concise account of the technical procedure necessary in the study of bacteriology, a brief description of the life-history of the important pathogenic bacteria, and a short account of the lesions accompanying the microörganismal invasion. As would be expected from the title, many interesting bacteria and protozoa are not considered.

The subject matter is divided into two parts. Part I consists of thirteen chapters, in which are considered topics on general bacteriology and technic, including the biology of bacteria, their cultivation, immunity, sterilization, disinfection, experiments upon animals, and the bacteriological examination of air, water, and soil. Part II, which occupies a major portion of the book, deals with the specific diseases and their bacteria.

These various subjects are treated in a very interesting style, especially for those who desire to acquire a general knowledge of the subject of bacteria and the *rôle* they play in the causation of disease. From the standpoint of a text-book for students, it is less fortunate. There is a looseness in the use of technical terms which tends to confusion rather than to definiteness. There are some statements of facts which may be questioned by other authorities, for example, the one referring to *Bacillus coli communis* as a *non*-motil organism possessed of flagilla. It is generally recognized that the greater number of varieties of this bacillus are motil, although less actively so than some other forms. Another unfortunate feature is the fact that special methods, which have appeared during the past two or three years, are generally omitted, while many of those contained in text-books are given.

In the description of the pathogenic species of bacteria, there is a lack of precision and uniformity of expression which are necessary for a student to easily comprehend the morphology and the essential and characteristic cultural properties of the different organisms. The illustrations are good, and many of the chapters, such as the one on immunity, are excellent. The very broad field covered in this book renders the omission of a discussion of many valuable and important topics a necessity. For this reason it is not a satisfactory text-book on technic, a complete manual of pathogenic bacteria, or a comprehensive treatise on pathology. It is doubtful if there is a need in our medical schools for a book of this kind. The author has, however, covered very well the ground intended to be discussed, and succeeded in making a very happy combination of parts of three great subjects.

OBITUARY RESOLUTIONS.

WEST END MEDICAL SOCIETY, NEW YORK CITY.

OCTOBER 3, 1896.

IT is with deep regret that we learn, at this our first meeting of the year, of the death of our esteemed fellow member, Dr. Edward S. Farrington, who died on September 7th of typhoid fever.

He was a man of fine character, scholarly attainments, and attractive personality, and was held in high esteem by all who knew him.

We feel that by his death both the Society and the individual members thereof have lost a valuable associate and a good and loyal friend.

We hereby resolve that these our expressions of regret and appreciation of our loss be spread upon the minutes of this Society, and that copies thereof be transmitted to his family and to the current medical journals.

CYRUS J. STRONG,
HOWARD GILLESPIE MYERS,
CHARLES GOOD,
EDWARD L. WILLIAMSON,
Committee.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 22, 1896, TO SEPTEMBER 28, 1896.

Captain Norton Strong, Assistant Surgeon, relieved from duty at Fort Sheridan, Ill., and ordered to Chicago, Ill., for duty as Attending Surgeon and Examiner of Recruits in that city.

First Lieutenant John S. Kulb, Assistant Surgeon, is relieved from duty at Fort Walla Walla, Wash., and ordered to Vancouver Barracks, Wash.

Captain William Stephenson, Assistant Surgeon, is relieved from duty at Vancouver Barracks, Wash., and ordered to Fort Sheridan, Ill.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, OCTOBER 31, 1896. No. 18.

ORIGINAL ARTICLES.

PERIPHERAL NEURITIS.[1]

BY ALEXANDER McPHEDRAN, M.D.;
ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF TORONTO, ETC.

I AM of the opinion that many cases of mild neuritis pass unrecognized, being usually looked upon as rheumatism, to the poison of which no doubt, in many cases, the occurrence of the neuritis is due.

Peripheral neuritis may be isolated, confined to one or a few nerves; or it may be multiple, symmetrical in its distribution, affecting the nerves of all the extremities. These peculiarities of distribution harmonize with the pathological changes occurring in each class. In the isolated neuritis, the disease begins in the nerve-sheath, constituting a "perineuritis" at first, the inflammation extending to the nerve-fibers later. In the multiple forms, on the other hand, the nerve-fibers are themselves the seat of the primary change—a "parenchymatous" neuritis, the sheath becoming affected later. These forms of multiple "parenchymatous" neuritis are always due to some virus in the blood, an organic or inorganic chemical compound usually, which may have a special affinity for nerve-tissue, and affects the periphery of the nerves, because these parts, being farthest removed from their nerve-cells from which they derive their energy, are least able to resist it. The occurrence of the poison in the blood accounts for the wide symmetrical distribution of the disease.

On the other hand, isolated neuritis is due to some cause acting locally, and if several nerves are affected their distribution is irregular, not symmetrical. In these cases there is always a constitutional cause at work as well, predisposing to the disease. In proportion as the constitutional condition is marked, the exciting cause produces the disease the more easily, and the number of nerves affected becomes greater and the attack approaches more nearly to a symmetrical one in character.

Alcoholic peripheral neuritis is the form most often met with, but it does not occur nearly so frequently in this country as in Europe, doubtless because with us much less stimulants are consumed by women than is the case in Europe. There the women are much given to regular indulgence in the stronger spirits, usually secretly, and such drinking appears to be more productive of neuritis than indulgence in occasional "bouts" of drunkenness. In men, delirium tremens is much more common, while it is rare in women. It is difficult to explain this difference; it is attributed to the fact that men drink beer rather than spirits. With us, however, spirit-drinking is more common and delirium tremens results oftener than neuritis. The cases of neuritis I have met, in which the disease was well marked, have all been among males. The following case is a well-marked example:

CASE I.—Wm. G., aged seventy-three, clock-maker. He has always been healthy. He came from Scotland when a young man. He says he has taken one or two glasses of brandy or whisky daily since he was ten years old, but never drank to excess. For the last twelve years he has lived alone, doing his own cooking, and has taken two or three cups of tea or coffee with each meal.

In June, 1893, while walking on the street, he noticed his legs became weak and his calves and feet numb—although he was only a short distance from home, he found it difficult to get there. In a day or two he noticed a similar condition in his hands and forearms. In five days he was unable to walk. He was admitted to the Toronto General Hospital, under my care, on July 6, 1893. His condition was as follows: Complete paralysis of the muscles of the legs and feet, the muscles of the thighs retained some power. There was foot-drop—the foot extended, and the toes flexed. Sensation to touch was much lessened, but great sensitiveness to painful impressions of any kind, especially on deep pressure. There was some "pins-and-needles" and burning feeling in the feet and legs, but not excessive, although sufficient to interfere somewhat with sleep. The skin was dry and harsh, the muscles flabby and tender. Knee-jerk was lost. The hands, forearms and arms were similarly affected, but to a less degree. He could use his hands slightly, but not sufficiently even to feed himself. He was rather dull and apathetic, but healthy-looking. There was gas in the stomach and bowels. The sphincters of both bladder and anus were weak. Urine was passed every two or three hours; this may have been due to enlarged pros-

[1] Read at the meeting of the Huron Medical Association, held at Clinton April 15, 1896.

tate, but the sphincter ani was undoubtedly considerably affected, and required many months to recover. The heart was enlarged and the arteries were sclerosed. The urine was pale and of low specific gravity, so that doubtless there was more fibrosis of the kidneys than would be accounted for by senile change. There was no reaction in either nerves or muscles to the galvanic or Faradic currents. Marked atrophy of all the muscles of the extremities followed.

On September 27th, nearly three months later, the following note was made: "Is gaining some power in both hands and feet; is able to flex toes slightly, but the foot is still markedly 'dropped.' There is slight response to Faradic current in the forearms." In January, 1894, he was able to sit up, and use his hands well, but they were weak. There was no pain, sensation was good in the hands, and fair in the feet. The toes were still flexed, and pressure to extend them caused pain, especially in the calf. There was complete control over the sphincter ani, but the urine was still troublesome, although control of it was improved.

He left the hospital the following spring considerably improved, but still unable to walk. He could stand with support, but the extension of the toes gave him pain in the feet and calves.

In this case the "pins-and-needles" sensation was not very marked for so severe a case, and there was not so much loss of mental power as is usual in alcoholic multiple neuritis; there was some dulness and apathy, but apparently no more loss of memory than age would account for. Otherwise the symptoms were very marked and typical. The weakness of the sphincter ani indicates that the neuritis extended into the lower part of the spinal cord. As he lived alone, confirmation of his statement of the quantity of spirit he took daily could not be obtained. He always told the same story, however, and seemed quite clear-headed. If his story is correct, it is difficult to see how the amount of alcohol taken could cause such extensive disease of the nervous system. Many men drink much more and just as regularly without disturbance of the peripheral nerves. The same is true, however, of diseases of other organs, of cirrhosis of the liver, for example. There must be some predisposing condition or some additional poison to enable the alcohol to cause such changes.

In the case of a man who entered the Toronto General Hospital seven years ago for alcoholic peripheral neuritis, the history differed materially from the foregoing case:

Case II.—He was about thirty-five years of age; drank freely, but irregularly; was exposed to changes of weather. He had been drinking heavily and slept out all night. It was early autumn, and the nights were cool, but without frost. He found his legs weak next day, with tingling in them, and he was soon unable to walk. The hands were slightly affected. When brought to the hospital he could neither stand nor walk, but could move the feet and toes while sitting or lying. On walking with support, the walk was ataxic. There was no atrophy. His mind was not materially affected, not more so than is usual in alcoholic cases. He made a complete recovery within three months.

In the first of these cases the symptoms are typical of peripheral multiple neuritis; the numbness and "pins-and-needles" sensations, the burning pain, the tenderness to deep pressure, the weakness accounting to complete paralysis in the most remote parts, the atrophy, the loss of superficial and deep reflexes, the loss of electrical reaction, together form a symptom-group that can not be misinterpreted. The absence of a history of excessive indulgence in alcohol, and of material mental disturbance, might be considered as ground for questioning it as one of alcoholic neuritis. Arsenic is the only other cause to which to attribute such an extreme attack. The mental apathy and the diminished pain discriminate this case from arsenical cases, as will be seen in the following examples of arsenical peripheral neuritis:

Case III.—A man somewhat over sixty years old had a rather deeply seated tumor below the left parotid region, which a so-called cancer-doctor pronounced a cancer, and applied a plaster. The plaster was reapplied several times at intervals of two or three days, followed by poultices. By this time numbness, with painful "pins-and-needles" sensations, appeared in the fingers, soon followed by similar signs in the feet. Weakness followed, and in a few days he was unable to walk or help himself. The numbness, pain, and tenderness also grew much worse. This was the history he gave when received into the hospital about two weeks after the appearance of the symptoms. His condition then was one of utter helplessness. The muscles of all the extremities were much atrophied, the atrophy being more marked in the feet and legs than in the thighs; and in the hands and forearms than in the arms. Ordinary sensation was lost in the feet and hands, and greatly blunted in the proximal parts of all the limbs, but there was great sensitiveness to painful impressions of all kinds. He was not able to bear even the weight of the blankets on the feet. There was a constant burning sensation in the hands and feet, especially at night, so that opiates were necessary to secure sleep. The skin was glossy, and desquamated rather freely, these changes being most marked in the peripheral parts. There was great sensitiveness in the muscles to deep pressure. The mental condition, in contrast to the alcoholic cases, was clear and active, as in health.

There was very little improvement for three

months. After he was able to stand, the feet were so tender that he could not walk, and the hands so tender that holding a cup to drink was painful. The foot-drop was not nearly so marked as in Case I. He left the hospital able to walk and to attend to his dress and other wants, although with much pain and difficulty. He returned some months later to have the tumor treated, considerably improved, but still far from well. The ultimate result I am unable to give, as he has been lost sight of.

Case IV.—A young man, aged twenty-two, blacksmith, entered the Toronto General Hospital September 29, 1894, under the care of Dr. J. L. Davison, who kindly permitted me to see the case. At five o'clock on the morning of September 8th, three weeks before admission, he ate some pie in the pantry at his boarding-house. Half an hour later he became nauseated, and on inquiry found that the pie had contained a large amount of "Rough on Rats," a mixture consisting of about fifty-per-cent. arsenious acid, which had been placed in the pantry to poison rats. An hour later he began vomiting, without straining. There was no pain but considerable depression with free perspiration. He worked until eleven o'clock. Then he sought advice, and was given emetics. He had no diarrhea. There was marked metallic taste in the mouth, no appetite. He felt fairly well next morning, and went out to sit in the sun. He soon became faint and perspired profusely. The breathing was slow. He lay down, sucked some ice, and soon revived.

At the end of the first week a tingling sensation began in the hands and feet; a few days later, trembling at the knees, with much weakness. He found it difficult to hold a cane. Hands and feet became very tender, and weakness increased. He lost flesh rapidly, especially in the extremities. There was much burning pain, most marked in the feet, and there were darting pains down the legs.

He was able to be about until September 26th, when he suddenly collapsed in the afternoon, and was unable to stand. He partially recovered in two days, and was able to stand again, but the power disappeared the next day, and he was unable to use his limbs or stand for eight months.

On admission to the hospital his extremities were much wasted. There was very little power in the arms, and still less in the legs. The skin was harsh and dry and desquamating. There was much numbness in both hands and feet. Ordinary sensation was almost lost, but there was great sensitiveness to deep pressure. Heat and cold were felt as painful impressions. All reflexes were lost. His mental condition was clear and active. Pain disturbed his nights.

The wasting, tenderness, and paralysis increased during the next few weeks, and two months later paralysis below the knees was absolute, and almost so below the elbows. The thigh-muscles were much wasted, but retained a little power. But pain was much less and only slight "pins-and-needles" sensations remained. His appetite and digestion were better. Reflexes of all kinds, including electrical, were, of course, absent.

Six months after poisoning improvement began, and has continued steadily since, so that now, eighteen months after taking the arsenic, he may be considered quite recovered. There is still slight numbness in fingers and toes, and the knee-jerk is absent. The muscles of the anterior tibial region of the right leg are still weak, and have not regained their full size. They react only to a strong current (Faradic). In walking the foot is easily turned under him, and he cannot raise the toes freely. All the other muscles have completely recovered.

This is a very remarkable case of arsenical neuritis, and a no less remarkable case of recovery from arsenical poisoning. To the dilution of the arsenic with the pie he no doubt owes his escape from a gastritis that would have proved fatal.

In both of these cases the history is typical of arsenical neuritis. In recovery also their course was regular—the power of motion returned before the electrical reaction, and the electrical reaction before the nutrition. It is interesting to observe power of motion gradually being restored long before the muscles show increase in size.

These cases also illustrate the remarkable recuperative powers of nerve-tissue. There had been extensive degeneration of fibers, requiring months to become complete, followed by months of apparent quiescence, and then came the signs of gradual regeneration, requiring many months to become complete.

To these cases I shall add one of mild neuritis, probably due to arsenic taken in medicinal doses. It was a case of pernicious anemia I published in the Medical News, October 11, 1890:

Case V.—Dr. P. was extremely ill with pernicious anemia. He had been vomiting incessantly when first seen. As soon as the stomach would tolerate it he was given liquor arsenicalis, 1 minim every three hours, and this was increased gradually until he took 45 minims per day. In two months he was able to return home. He was directed to intermit the medicine for a few days from time to time, but in his anxiety to make a complete recovery, he took it continuously. In the third month of taking the medicine numbness and tingling of the hands and then of the feet began. After two or three weeks sudden advent of pain and a purpuric rash occurred. When seen about two weeks later, the anesthesia and tenderness were sufficiently marked to make the hands awkward and walking irksome. It took about three months for him to recover.

The recurrence of neuritis as the result of medicinal use of arsenic is not very rare; nevertheless,

the drug is often given even more freely than in this case without any toxic effects. The sudden onset of general pains and the purpuric rash indicate the existence of some other poison in the blood, possibly of a lithemic or rheumatic nature, and this, or the toxic agent producing the pernicious anemia, may have caused the neuritis. I have a patient under observation at present in whom peripheral neuritis occurs in connection with pernicious anemia.

Case VI.—A married woman, aged forty, of good family and personal history, has been ailing for over two years, growing gradually more anemic. She lost a daughter last year, after which her condition grew much worse. I saw her first on January 4, 1896. She was then very prostrate, her body fairly nourished, but her limbs were much wasted. She was unable to sit up. On careful repeated examinations the blood was found to contain only between 400,000 and 500,000 red corpuscles per c.mm., and hemoglobin twenty-two (Fleischl). There was some numbness with tingling of the hands and feet. The following week she had great pain and considerable swelling in the feet, the right being most affected. The feet and legs were partially anesthetic, and very tender, especially to deep pressure. It was thought at first that probably phlebitis was the cause of these symptoms, but there was no special tenderness along the course of the veins. The temperature varied from 99 to 102° F. There was some improvement in a few days, and, within a month, the pain and swelling had disappeared, but the numbness and tenderness persisted and have not wholly disappeared yet. Her general condition has greatly improved, the blood-count being now over 3,000,000 corpuscles per c.mm. Sensation is not yet normal, and the legs especially are still much wasted. She is able to walk a little, but the knee-jerk is absent, and there is no response to a strong Faradic current below the knees, and only faint response in the forearms.

The cause of the neuritis was probably the same poison in the blood that caused the destruction of the red corpuscles. I have not met with a case of multiple neuritis occurring in pernicious anemia before this one, nor have I found it referred to in the literature of that disease. It is just possible that in Case V. the neuritis was due to the poison of pernicious anemia and to the arsenic. In isolated peripheral neuritis a local exciting cause is the chief consideration, and is of importance in proportion as the neuritis is circumscribed, even in these cases, however, a predisposing condition probably always exists. Of these predisposing causes it is known that gouty and rheumatic conditions are among the most frequent. Lithemia should be added to these as probably one of the most frequent causes rendering the nerves liable to become inflamed from slight local causes, such as cold and traumatism. Patients seeking advice for "torpid" liver, dyspepsia, constipation, etc., not infrequently complain of numbness and tingling in a hand, a foot, or some other part. They are usually much concerned about these symptoms, fearing that they may be the precursors of paralysis. Lithemia is probably the most frequent predisposing condition leading to the development of inflammation of the nerves, after injury to them, as often occurs in dislocation of the shoulder.

In the treatment of this disease, the first duty, of course, is the removal of the cause—the "etiological treatment." The cause may be easily demonstrated, when, as in most cases, it is alcohol, lead or arsenic; it is more obscure in uric-acid poisoning, and in diabetes. For the neuritis we have no specific remedy. Anodynes may be required to relieve the pain. Rest and protection of the parts from injury are of importance.

Strychnin is regarded by some as a specific, and some satisfactory results are reported from its use, especially by subcutaneous injection gr. $\frac{1}{20}$ to $\frac{1}{30}$, twice daily. It favors the return of normal nutrition by stimulating the irritability of the affected muscles. Probably it also stimulates the multipolar cells of the spinal cord, so that they may impart greater energy to their fibers, and thus enable them to resist further destruction and hasten repair in those already degenerated. Electricity may, to some extent, effect the same purpose, but it is doubtful if it has any further effect than to stimulate contractions of muscles, if they react to the stimulus.

As soon as tenderness has abated massage and baths will prove useful in hastening the removal of excrementitious matter, and stimulating the nutrition by increasing the flow of blood through the affected parts.

In the later stages the rousing of the patient's latent energies and encouraging him to make voluntary use of the muscles, as far as possible, will do more to accomplish the objects in view than any other plan of treatment.

With few exceptions the prognosis is good; recovery will be long delayed in severe cases, and in a few acute cases a fatal termination occurs within a few days or weeks. In the first case I have related, full recovery did not probably take place on account of age.

Bad cases grow worse for weeks or months and then remain stationary for a time. Complete recovery requires several months.

VAGINAL SECTION FOR THE CURE OF RETROVERSION OF THE UTERUS.[1]

By HENRY T. BYFORD, M.D.,
OF CHICAGO;
PROFESSOR OF GYNECOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO, AND POST-GRADUATE MEDICAL SCHOOL OF CHICAGO.

From the time Schuecking attempted the cure of retroversion by vaginal ligature, much ingenuity has been displayed by gynecologists in Germany in devising methods of treating retroflexion and retroversion by vaginal section.

A number of successful and unsuccessful attempts have been made to shorten the sacro-uterine ligaments by ligatures passed through them[2] by the same method; including, however, the denuded cervix in the sutures, so as to unite it to the denuded posterior vaginal wall;[3] by the obliteration of the cul-de-sac of Douglas;[4] by the same method, but passing the sutures through the cervix;[5] by suture of the ligaments themselves through an incision into the cul-de-sac;[6] and finally by suture of the ligaments through an opening made between the uterus and bladder.[7]

The attempts, however, have not proved uniformly satisfactory, since it is difficult to reach the ligaments by way of the vagina, and there is too much subsequent traction on the parts operated upon.

Mackenrodt made a median-line incision in the anterior vaginal fornix, separated the bladder from the uterus and vagina, and sutured the anterior uterine wall to the vaginal wall behind the bladder, which was displaced forward. Some vesical symptoms and recurrences of the retroversion led him to go one step farther, *viz.*, open the peritoneal cavity between the uterus and bladder, and suture the uterus direct to the vaginal walls, thus obtaining a connective-tissue union between the uterus and vagina, instead of partly peritoneal adhesions as in his first method. After operating over a hundred times, he discovered that the connective-tissue union of the anterior vaginal wall with the anterior uterine wall interfered with the development of the latter during pregnancy, to the extent of interrupting pregnancy in some cases, and of seriously complicating labor in others. He therefore declared the procedure unfitted for patients liable to become pregnant. Dührssen makes a transverse incision in front of the cervix, separates the bladder from the uterus, incises the peritoneum in a sagittal direction, and draws its edges and the fundus uteri to the vaginal edges by one or two sutures, but closes the peritoneal incision, before tightening and tying them. The fundus thus adheres to the bladder instead of to the vagina.[1]

Mackenrodt's bad after-results led some operators to return to the first method of peritoneal attachment without opening the peritoneal cavity, and determined him to stitch the uterus to the bladder only in his subsequent cases. Simultaneously, several operators began to use the round ligament as the means of support.

Wertheim[2] of Professor Schauta's clinic in four cases attached the round ligaments, one or two centimeters from the uterine end, to the vaginal edges; and also proposed attaching them to the peritoneal edges where the membrane is reflected from the bladder, but did not have much faith in the latter as a permanent cure. In one case he made a loop in the round ligament by passing a silk thread through it near the uterus, and then again through it as far away from the uterus as possible and tying it.

Bode[3] of Dresden had already performed the same operation three times, and recommends it.

Guenther[4] of Dessau put a silk suture in each round ligament near the uterus and pierced the abdominal wall over each tuberbuculum ossis pubis with the needles, and thus brought out the threads, pulled the uterus forward by them, and tied them on the skin. He had performed the operation once.

F. Kiefer[5] of Martin's Clinic in Berlin stitched together a fold of the ligament through the vaginal incision very much as Mann does through the abdominal incision. He also proposed suturing the round ligaments near their uterine ends to the abdominal walls, but his method differs from Guenther's, in that he penetrates the abdominal walls from without, guarding the point of the needle by his finger, which has been introduced through the vaginal wound, and pulls the thread down into the vagina, attaches it to the scarified round ligament, and then draws the uterus to the abdominal walls by means of it.

While performing the operations, gynecologists discovered that through the same incision adhesions could be separated, diseased ovaries and tubes resected or removed, subserous uterine

fibroids enucleated, and small omental tumors, or portions of the omentum itself, be extirpated.

Working along the same lines and at the same time with these followers of Dührssen and Mackenrodt, I had evolved a method, before the reports of the above-mentioned work were known or accessible to me, which I think places the uterus more securely in its proper position than any of them, and at the same time does not interfere with its normal mobility, nor with that of the bladder. It consists in producing limited peritoneal adhesion between the fundus uteri and the bladder, and in shortening the round ligament through the vaginal incision. The bladder-attachment acts as a safeguard, in that it insures a return of the fundus forward, while the contracting bladder is emptying itself.

The technic of the method is about as follows: The vulva and vagina are thoroughly scrubbed with soft soap, then with strong alcohol, and then with a 1–2000 solution of bichlorid of mercury. The uterus is dilated and curetted, and disinfected with mild or strong solutions according to the requirements of the case, or the notions of the operator. This preparation is necessary to prevent the infection of the connective tissue and buried ligatures.

A transverse incision, a trifle over an inch long, is then made in the vaginal wall just in front of the cervix, and the bladder separated from the uterus by the finger as far up as the peritoneal reflection. Then a longitudinal vaginal incision, about two inches long, is made in the median line from the neck of the bladder to the middle of the transverse incision. The bladder is separated from the vagina for a short distance on either side of the incision to give room for manipulation. The peritoneum is then torn across between the uterus and bladder, an intra-peritoneal pelvic examination is made, adhesions are separated, and such parts are treated or removed as may require it. The bladder-peritoneum is then seized by forceps and drawn down by successive grips, until that which lies behind the tubes can be seen. Two chromicized catgut-threads are introduced about one inch apart through this portion of the peritoneum and subperitoneal tissue as high as possible. Then the anterior surface of the uterus is grasped with tenaculum-forceps, and the fundus pulled into the vaginal wound and attached to the bladder by means of the above-mentioned catgut-threads. The finger is next hooked over the left round ligament, which lies beside the vaginal wound, a loop of the ligament drawn into sight, grasped by forceps, and pulled down until the inguinal end is taut. A catgut-suture is put through it as far from the uterine end as possible, and is made to attach it to the uterus just above the normal uterine insertion, which is easily exposed to view by the vaginal retractors. The same is done to the right ligament. The entire vaginal wound is closed with transverse sutures that reunite the bladder to the vagina, and also draw the ends of the transverse incision together, leaving one row of sutures in the median line. This lengthens somewhat the anterior vaginal wall and draws the connective tissue together in front of the cervix. A few inches of a narrow strip of gauze is placed in the connective tissue in front of the cervix to be removed in twenty-four hours, by pulling on the end which projects between the sutures into the vagina.

I have operated upon ten cases in this way, besides one case in which I merely sutured the fundus over the bladder, and in each one the uterus has remained in a normal, mobile position, without the aid of a pessary at any time. The comfort is greater, and the complaint much less than after Alexander's operation, and the patient is not conscious of a wound or sore place. In addition to these advantages we obtain, while operating, a definite knowledge of the condition of the pelvic organs and the possibility of correcting them.

The uterus has no abnormal attachments except the two points of peritoneal adhesion to the bladder, and there is nothing to fear from subsequent pregnancy.

THE DOSAGE OF NITROGLYCERIN.

By W. L. ARMSTRONG, M.D.,
of New York.

The dosage of nitroglycerin does not seem to be very clearly defined in medical literature. That poisonous effects may sometimes be obtained from small doses all observers recognize. Dr. H. C. Wood cites a case in which a single drop of a one-per-cent. alcoholic solution produced insensibility, and another case in which two drops caused complete loss of consciousness and of the pulse at the wrist. That the continued use of the drug creates a tolerance is mentioned by Dr. H. A. Hare, who says: "It is noteworthy that patients rapidly become immune to the drug, and Reading has recorded a case in which, after a year of treatment, one dram of a ten-per-cent. solution was taken daily, with good effect" (*i. e.*, six grains in the twenty-four hours). The largest recorded dose that I can find is one reported by Dr. Whittaker, in the "Twentieth-Century Practise," of $1\frac{1}{10}$

grains every three hours, or 8$\frac{4}{5}$ grains in twenty-four hours.

Nowhere in the literature of the drug do I find even a suggestion that a contracted state of the arteries produces a condition which tolerates larger doses of the drug than when the arterial walls are in their normal state. Arguing from a slightly different standpoint, the proposition may be formulated that the poisonous symptoms of nitroglycerin do not begin to manifest themselves until the drug has relaxed the arterial walls beyond their normal tonicity. In confirmation of this theory, I submit, through the courtesy of Dr. Beverley Robinson, the following three sets of experiments, which were carried out, last winter, at St. Luke's Hospital. For the smaller doses, tablets of nitroglycerin were used, and for the larger doses a ten-per-cent. alcoholic solution. This solution was subjected to a quantitative analysis by a competent chemist, and found to be of full strength.

To six patients with normal arteries and hearts nitroglycerin was administered in the dose of $\frac{1}{100}$ of a grain, every hour. After three or four doses, in several of the cases, and before the expiration of twenty-four hours in all of the cases, headache was produced. In other words, a total dosage of about $\frac{1}{3}$ of a grain in the twenty-four hours caused poisonous symptoms.

The second experiment can scarcely be called such. There was a patient in the male ward with well-marked atheromatous arteries, but no tension. He had never taken any nitroglycerin in his life, to his or my knowledge. By mistake, he was given, at a single dose, 2½ grains of glonoïn. This large dosage was followed by absolutely no discomfort whatsoever. In this case, apparently, the rigid condition of the arterial walls did not permit the nitroglycerin to produce its relaxing effect, and so no poisonous symptoms occurred.

The third set of experiments was tried on cases of marked arterial tension, the walls being free from atheroma. The first case was a man, fifty-three years of age, who had been troubled for ten years with severe attacks of asthma. The physical examination revealed loud, sibilant, and sonorous sounds, subcrepitant and moist râles over both lungs, and marked tension in the radials. The urine contained a trace of albumin, and, at times, a few hyaline casts. During twenty-five days the nitroglycerin was gradually increased, so that finally he was getting seventy-six grains in the twenty-four hours. All the signs had disappeared from the chest, the breathing was easy, there was no tension in the radials. At no time during the administration of the glonoïn did he suffer from headache or any symptom that could be attributed to the action of the drug. The medicine was then stopped, to observe what the effect would be. Within forty-eight hours he had a return of his asthma and radial tension. Another case of arterial tension was that of a man, twenty-one years of age, who had had symptoms of nephritis for ten weeks previous to entering the hospital. His urine contained ten per cent. of albumin and numerous granular casts. His radials were markedly tense, but free from atheroma. During four weeks the nitroglycerin was steadily increased, so that he finally took 125 grains (over two drams!) in the twenty-four hours. The tension had entirely disappeared, and no unpleasant symptoms had presented themselves. The final dose was eight grains every hour while awake. Upon increasing the dose to nine grains, a slight headache was produced, and the drug was pushed no farther. It should be stated that in both of these cases of high arterial tension the relaxation of the radials was obtained some little time before the maximum dosage was reached. The drug was increased from that point simply to observe the degree of tolerance.

The above results point to the following conclusions in regard to the dosage of nitroglycerin:

1. It is only when dealing with arteries in which there is no more than the normal tonicity of the walls that the drug is liable to produce disagreeable effects. Under this condition it should be administered with caution and in small doses.

2. In cases of arterial tension, the drug can be used more freely than has been customary among practitioners, the dose being proportioned to the degree of tension.

3. In cases of arterial tension, tolerance to the drug is rapidly acquired, and, by a slight increase day by day, very large doses can soon be taken with safety, the constant guide being the degree of tension in the arterial wall.

CLINICAL MEMORANDUM.

UNILATERAL PARALYSIS OF THE SPINAL ACCESSORY NERVE CAUSED BY EXPOSURE TO COLD, ASSOCIATED WITH MOTOR PARALYSIS OF THE VAGUS.

By THOMAS HUBBARD, M.D.,
of Toledo, Ohio.

Paralysis of the spinal accessory is evidenced by paresis of the sterno-mastoid and trapezius, both of which are also freely supplied with motor nerves from the cervical plexus. These muscles are weakened in power,

only the occipito-acromial fibers of the trapezius being paralyzed; according to Osler.[1] The scapula droops and rotates downward and outward, and power to elevate the arm above the shoulder is more or less impaired. Thus it is observed that, in so far as the cervical muscles are concerned, the evidences of spinal accessory paralysis are not pronounced and may be readily overlooked.

In the sub-occipital space, where the nerve emerges from the sterno-mastoid, it is quite vulnerable to cold. Compared with the facial in its temporo-maxillary portion, one would expect it to be equally susceptible to the influences of exposure. The association of progressive and complete paralysis of the spinal accessory and pneumogastric is not rare, but such conditions are nearly always central in origin, usually bilateral and permanent.

Having observed several cases of obstinate unilateral paralysis of the laryngeal muscles that could consistently be attributed to exposure to cold, the suggestion of analogy to facial paralysis has often presented itself. We must, of course, exclude all of those cases of myopathic origin in which inflammatory infiltration causes the impairment of function. Again, as McBride states, the rheumatic condition is very often a predisposing factor in transient paralysis of the intrinsic laryngeal muscles.

We would not expect to find a unilateral paralysis from exposure of the pneumogastric or its motor branches, but rather from traumatism, pressure, or chilling of the peripheral portion of the spinal accessory and consequent functional disorder of all its branches.

The following case, in which the group of symptoms pointed clearly to the condition implied in the title, recently came under my observation:

The gentleman, a druggist, of about forty years of age, returned from a two weeks' lake-trip on August 30, 1895. One week previous, while stopping at Marquette, and after several days' exposure to strong winds yachting on Lake Superior, he had severe neuralgia in the right temporal region. The following morning he awakened with strange and annoying sensations in his throat, and when he attempted to move he found that his right arm was weak, and the head seemed very heavy and inclined to fall over to the left. With assistance from his wife he dressed and went to breakfast. He soon discovered that he could swallow only with difficulty. The bolus of food seemed to stay in the lower pharynx for some time and passed into the gullet slowly. Fluids were in part returned into the mouth. At times he choked quite badly. He observed also that it was difficult for him to raise the right hand toward the mouth.

During the day there was some cough, but it was not severe at first. The patient states that he did not feel as though he had contracted a cold, and rightly, I think, attributed the laryngitis to the irritation of food and drink. His general condition was fairly good, and he continued on his lake-trip, making occasional stops. Several times he had severe attacks of choking, and gradually a mild bronchitis developed. When asleep he snored very badly. By the time he reached home he was anxious and depressed. It should be added that his habits are excellent, and there is no history indicating a rheumatic diathesis, nor malaria, nor constitutional disease.

I examined him August 30th, and found the following condition: Temperature normal, pulse about 95, stomach and bowels inactive. The urine was normal. Reflexes, including pupillary, active. Sensation, both of skin and mucous membrane, was natural. The action of facial muscles and lips was good, and the tongue was protruded vigorously, with a slight inclination to the right. The uvula was drawn over to the left side, and a contraction-dimple was observed on the left, while the right side was drawn smooth. The action of the right pharyngeal muscles was decidedly impaired. The right vocal cord was fixed in the cadaveric position, and the left made compensatory excursion sufficient to produce a fair voice. The mucous membrane over the right arytenoid was infiltrated and looked excoriated or blistered, doubtless from irritating foods. He was coughing quite badly, and on such occasions there was decided inspiratory stridor. Dr. C. L. van Pelt called attention to the fact that the trapezius and sterno-mastoid were paretic. Reaction-tests were not made, but trials of range of motion and strength located the weakness in these muscles. The arm and forearm seemed to have normal strength. The head was supported most of the time on the right hand, with the elbow rested. The mind was clear and, as stated, the voice was weak and tremulous, conversation tiring him quickly. The impaired action of the tongue was doubtless due to lack of normal support at the base. During his confinement to the house the pulse varied. At times it was as low as 50, and on excitement would run up to 95, thus suggesting that the cardiac function of the vagus was disturbed.

The treatment consisted of quiet rest, mild cathartics, bromids, and codein to quiet the spasmodic cough, and the diet was restricted to warm, bland fluids. A mild, detergent gargle was prescribed.

On the second day following, I was summoned in great haste. He had had a desperate attack of choking while taking a little plain soup. For five minutes or more, he struggled violently to catch his breath, which left him much exhausted and frightened. The bromids were increased, and nitrite of amyl was supplied to give him renewed confidence. This attack marked the critical period of his sickness, and from that day he gradually improved. For about two weeks he would throw his head over to the left with each attempt to swallow, thus rendering the palato-glossal and right pharyngeal muscles more tense. The base of the tongue was probably called into action to crowd the bolus into the gullet. He was confined in all about two weeks after he reached home, but the weakness of the throat and shoulder persisted for about a month from the date of his return home. A recent examination shows that all of the paretic symptoms have disappeared. As stated, the right vocal cord seemed to be completely paralized in so far as phonation under examination with the laryngoscope could determine, but yet there was probably some motion in ordinary speaking. This is possibly suggestive of independent but limited motor function of the pneumogastric.

SPECIAL ARTICLE.

LEPROSY IN BRAZIL.

By ALBERT S. ASHMEAD, M.D.,
OF NEW YORK.

Dr. José Lorenzo de Magalhaes of Brazil, who has published an interesting work on leprosy in that country, says that this disease did not exist among the natives, and that it does not exist to-day among those who are not yet mixed with the rest of civilized mankind.

Dr. Juliano Moreira, physician to the Hospital Santa Isabel, Bahia, Brazil, informs me that the natives, before the Portuguese colonization, the Tupis, Krars, the Goytacazes, the Guerens, Gucks, Parecos, the Guaycurus, Lengoas, and Arrawacks, were certainly not leprous, and that the Brazilian Indians of to-day are not afflicted with this disease.

Dr. Enrique Robelin, speaking of leprosy in British Guiana, says: "It seems that leprosy was imported by the negro slaves, among whom a leprous epidemic broke out, and as special care was taken to isolate them, the evil was limited and circumscribed among themselves. In 1831, there were 431 lepers, who were all sent to the leprosery situated on the Pomeroon River. In that place had resided since time immemorial various Indian tribes, among others were the Caraibs, the Arrawacks, and the Warrows. Disgusted by this neighborhood, the Indian tribes left the territory, except the tribe of the Warrows. What happened to both parties? The tribe of the Warrows, which remained in the vicinity of the lepers, with whom they established relations, *was infected by leprosy*. The other tribes, whom an instinct of self-preservation had induced to leave the country, and to take refuge in other districts, remained intact (Dr. Suzor, 1886)."

Speaking of the development of leprosy following human currents, Dr. Robelin says: "What means this propagation every time that new colonists came into close contact with the inhabitants? Is it heredity or spontaneity? Heredity is unable to explain this great development, spontaneity still less. These reasons are not solid, they fly in the face of good logic, and are in contradiction with the facts which we have exposed above. Hereditary diseases do not run so rapidly through the world, or through the countries."

The same contrast is offered by Brazil. Leprosy is very common in the provinces of Maranhao, Para, Pernambuco, Bahia, Rio Janeiro, and Parana; it exists also in the southern provinces of Las Minas and San Paulo. The Indians of Brazil do not suffer from it.

Leprosy, contrary to the assertion of E. R. Coni, is not called quigila in Brazil, but morfea.

Quigila, although it exists in Brazil, is far from being as frequent as morfea or lepra, and is therefore less studied.

LEPRA ANESTHETICA.	QUIGILA.
1. Vesicles presenting the character of the herpes zona or of the pemphigus, which burst spontaneously, issuing first a clear and transparent liquid, and leaving in their place ulcers which exhale a fetid and sanious pus. It is one of the characteristic symptoms of the disease.	1. Plaques of psoriasis, which at times present the aspect of ichthyosis.
2. The skin presents anesthesia almost from the beginning of the disease, and this is one of its culminant symptoms.	2. The skin presents anesthesia in no period of the disease.
3. Affection generally considered as local, but with tendency to generalization.	3. General affection.
4. It is not contagious, according to modern authors.	4. Contagious, affecting sometimes all the members of a family.
5. It appears between the ages of thirty and fifty.	5. It appears before thirty, and begins its work mostly at twenty.
6. Its average course is of eighteen years, while there are examples of twenty and thirty years' duration.	6. The course of the disease is rarely five or six years.
7. The skin of the face is normal.	7. The skin of the face, forehead, and eyelids is swollen and hardened.
8. The mucous membranes are always found intact.	8. The mucous membranes are frequently attacked.
9. The bones are eliminated entirely or carious.	9. The diaphysis of the bones of extremities disappears, molecule after molecule, by interstitial reabsorption.
10. The mouth is asymmetrical, turned to one side by the paralysis of the buccinator.	10. Symmetrical mouth.
11. Disturbance or abolition of vision.	11. Normal vision.

Ainhum was first described by Drs. da Silva and Wucherer, physicians of the province of Bahia, Brazil.

In the course of 1876, we observed a case of this affection in a Moreno, born in the island of Bourbon. He belonged to the clinic of Dr. Juan Antonio Argerich.

In this patient, the fourth toe of the right foot was amputated. We could observe the symptom-complex of this disease, such as the furrow at the root of the toe, the deformity, intense pains, and incapacity of walking.

We may therefore offer the following table of symptoms which shows strikingly the notable difference existing between the two diseases:

AINHUM.	LEPRA ANESTHETICA.
1. Affects only negroes and Hindoos.	1. Affects individuals of all races.
2. Affects only the last toes.	2. Affects all toes and fingers.
3. Hyperesthesia.	3. Anesthesia.
4. No muscular atrophy.	4. Muscular atrophy.
5. No initial vesicles, no ulcerations nor retraction of tendons.	5. Begins quite regularly with vesicles, followed by ulcerations, more or less deep, and retraction of tendons.
6. In the case observed by us, the bones were found whole, and a little more vasculated.	6. The bones are carious and fall off spontaneously.
7. There is always a furrow at the base of the fingers with thickening of the skin.	7. Never any furrow, no thickening of the skin.
8. The patient cannot walk without pain.	8. He walks without pain.
9. Vision remains.	9. It is disturbed or destroyed.
10. The finger is never in any period sphacelated.	10. Finger or fingers often so.
11. The affection is localized only in the fingers, and the prognosis is not grave.	11. The affection penetrates to the centers and is of great gravity.
12. May be cured by the amputation of the finger, and sometimes by the deprivation of the ring.	12. Always incurable.
13. No general phenomena.	13. There are general phenomena.
14. Nutrition generally intact.	14. Deep perturbances in the nutrition of the whole organism.
15. No complications.	15. Generally complicated with renal lesions which offer all the symptoms of albuminoid nephritis.

From Dr. W. Havelburg, physician to the Hospital Don Lazaros, Rio Janeiro, and director of the bacteriological laboratory, I have received a history of his hospital, which treats of the expansion of leprosy.

In the seventeenth century, or perhaps the last years of the sixteenth century, lepra appeared in Rio Janeiro, borne on the tide of immigration from Europe and Africa.

The disease propagated itself quickly, attacking all races and classes, but especially the black race.

The harbors of disembarkation for the Africans, like Angra dos Reis, Macahé, and Campos, furnished a large contingent of black lepers, employed in the rural service.

There is in Rio Janeiro an increasingly large number of lepers, most of them poor, but some of them well-to-do, and this number will increase further if the public powers do not take energetical measures to restrict it.

MEDICAL PROGRESS.

Treatment of Chlorosis by Rest.—In a comprehensive article on anemia, published in the *Brit. Med. Jour.* of September 19, 1896, TAYLOR compares the use of iron in chlorosis to that of digitalis in heart-disease, saying that just as in the severer forms of the latter trouble digitalis is useless unless the heart is saved some of its exertion by physical rest, so iron may be of little value in grave cases of chlorosis if the wear and strain of the body is not reduced to a minimum. This is no new point, but it will bear repeating, because of the widespread tendency to insist upon fresh air and exercise for every anemic patient. The value of fresh air is intelligible, and in so far as the chlorosis can be shown to be due to indigestion, and in so far as the exercise may improve this condition, it may be advisable; but in certain conditions it may be shown to be harmful. In late stages of anemia, when the heart is dilated and the patient panting for breath after the least exertion, the attempt to keep up systematic exercise only prolongs the illness. Taylor has seen many cases which had been treated with iron and exercise with only temporary benefit, permanently improved by rest in bed for one, two, or three months, according to the gravity of the case.

A New Method for the Application of Medicines to the Nasal Mucous Membranes.—LIEBREICH (*Therapeutische Monatsschr.*, August, 1896) makes applications to the mucous membrane of the nose in the following manner: A bit of absorbent cotton, corresponding in size to the anterior nares, is saturated with the prescribed fluid. It will hold readily 30 to 40 drops. It is then inserted into the nose so far that it does not protrude, and while the patient breathes with the mouth open, light pressure is made upon the alæ of the nose with thumb and forefinger, the pressure being made from before, backward. This will serve to express the fluid and effectively douche that side of the nose. The simplicity and safety of this method of treatment especially recommend it. The position of the head during the douche is immaterial, and need not be altered, therefore, from its customary one. By experiments upon the cadaver, Liebreich found that 1 c.cm. of fluid introduced into the nasal cavity in the manner described, the head being held in a vertical position, bathed the mucous membrane of the inferior meatus and inferior turbinate and, to a less extent, that of the middle turbinate, depending upon the configuration of the nasal cavities.

THERAPEUTIC NOTES.

Non-Tubercular Chronic Diarrhea of Infants Treated by High Injections.—DAUCHEZ (*La Presse Méd.*, July 25, 1896) advocates the use of large irrigations of warm boric-acid solutions in non-tubercular chronic diarrhea of infancy. By this means the infectious agents, ferments, and microbes, which settle especially in the large intestine, are washed away. If desired, a two-per-cent. solution of hyposulphite of soda, or of nitrate of silver 1–2000, may be introduced high up into the rectum by means of an esophageal or urethral catheter of large caliber.

These injections should be made every day, or at least, every second day, alternating, in the latter instance, with a periodical or methodical treatment by means of purgatives (sulphate of soda, or magnesia, or calomel, associated with betanaphthol or salol). Later (from the sixth to the fifteenth day), opium and subnitrate of bismuth will complete the cure.

The investigations of Gilbert and Dominici have shown that purgatives reduce from fifteen billion to two or three billion the organisms found in the intestines in such cases —coli bacilli, spirilli, amebæ, etc. The stools, owing to the action of these intestinal microörganisms, are very fetid—brown, or green, and fluid—mixed with glairy secretions which adhere to the napkins. There are usually only four or five a day, without blood, or membranous flakes, or rice-grains, as in dysentery, without tenesmus, pain, meteorism, or any gastric trouble.

Dauchez agrees with many others who have recently investigated such cases that the usual cause of infection is impure drinking-water. He quotes from a number of clinical records of patients cured in from two to four days of long-standing chronic diarrhea by irrigation of the colon. In introducing large quantities of fluid the pressure should be slight (one to three ft.) and the fluid should enter the colon slowly, while the patient lies on his back with a pillow under the left hip so that the cecum may be low.

The Treatment of Lupus.—FEIBES reports excellent results from the local treatment of lupus vulgaris with a solution of one part of metallic mercury in two parts of fuming nitric acid. The application may be made by means of a small bit of wood, pointed at one extremity, which is dipped into the solution and plunged into the lupous nodule. Ten or a dozen nodules may be thus treated at one sitting, which is repeated every three or four days. The little wounds are covered with cotton, which is removed with the aid of a borated solution on the following day and replaced by lead-plaster. The resulting cicatrices are very small.—*Semaine Médicale*, 1896, No. 30.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

Subscription Price, including postage in U. S. and Canada.

Per Annum in Advance	$4.00
Single Copies	.10
With The American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, OCTOBER 31, 1896.

EFFICACY OF SULPHUR-DISINFECTION.

An English health officer, Dr. Kenwood, wearied of hearing the disinfecting of rooms by sulphurous-acid gas referred to as "inefficient," "unscientific," and "useless," undertook experiments to determine the truth of such assertions. His results and conclusions are published in the Medical News, September 5, 1896, p. 277.

Referring first to statistics of parts of London and its vicinity, he found that in 1895 there were 1330 premises disinfected by sulphur for either diphtheria or scarlet fever. In fifty-five instances (four per cent.) one of these diseases broke out in the same premises within two weeks after disinfection. As several causes other than that of faulty disinfection of the room combine to make up this small percentage, the author looks upon these figures as proving the value of sulphur. Thus, infection may have antedated fumigation, or it may have occurred from improperly disinfected clothing, or from a totally outside source.

But not satisfied with statistics, Dr. Kenwood turned to experiment, and exposed fresh diphtheria-bacilli on swabs and lint in a closed room, in which sulphur was burned just as it would be in official disinfection, *i. e.*, one pound of sulphur to every 1000 cubic feet of air-space. When this amount of sulphur was burned, the air tested four hours later was found to contain 0.88 per cent. of SO_2. Other tests were made with less amounts of sulphur, so that the air contained only 0.5 per cent. and 0.25 per cent. of SO_2 respectively. In the twelve tests made where one-half pound of sulphur or more was burned to each 1000 cubic feet of space, no growth could be obtained from the cultures. In the twelve tests made by using sulphur (liquefied SO_2), only sufficient to give a percentage of 0.25 in the air, one weak diphtheria-culture was obtained growing after three days' interval. In two other instances aerial bacteria were obtained. Control-cultures in every case grew vigorously.

Dr. Kenwood concludes therefore that for the germs against which it is employed sulphur-disinfection is efficient, and possesses over the method of rubbing down or sponging the walls, employed in Germany and France, one notable advantage, in that through carelessness the workman cannot neglect any part of the wall, as may easily be the case where the continental methods are used.

IMPORTANCE AND USES OF HYPNOTISM.

Another universal panacea has been thrust before the attention of the public in a popular journal. We can quite agree with Dr. R. Osgood Mason, when he says, in the *North American Review*, hypnotism has come to stay, but we cannot agree with him in the abounding confidence which enables him to prophesy that its investigation and application will disclose new uses, therapeutic, psychic, and educational, which will place it among the most highly prized agents for good in use among intelligent well-wishers of humanity. That "suggestion" may be made to serve many good purposes, stimulating the weak along the path of moral rectitude, inhibiting lower impulses, now and then subserving the purposes of a therapeutic agency, we do not deny. We believe, however, that the first object of an article, particularly one by a medical man, recommending a new therapeutic or pedagogical agent, should be clearly to distinguish between those cases in which it is ser-

viceable and those in which it is not; and when such an article appears in a popular journal, universal promises should not be extended which may postpone the initiation of individual effort in a moral or intellectual sphere, or may delay recourse to proper medical treatment. The evil of all mind-cures lies in just this, that the unthinking public fails to distinguish the very marked line of separation between the cases in which the influence of the mind may act in a remedial manner, and those cases in which its influence can produce no beneficial change whatever.

It is demanded, from a medical man especially, that attention should be called to the fact that susceptibility to hypnotic influence is itself a stigma of neuroticism, perhaps of hysteria, and that those cases in which hypnotism has been effected have this in common with cases of mind-cures, that they are most frequently observed in hysterical subjects whose symptoms are significant of a disorder of the mind. Far from doing this the author suggests that nearly every one is to a greater or less degree susceptible to hypnotic influence. Nearly every one can be made sleepy by looking at a bright object fixedly, while some one else strokes his brow, pats his hand, makes monotonous passes in front of his eyes, or utters rhythmical sounds. But that nearly every one can be put into such a state, that the cigarette- or drink-habit can be suggested away, or that nocturnal terrors, insomnia, stammering, or immorality can be done away with, has not been proved by a careful study of such hypnotic cases as we possess.

Continued hypnotization may only injure the subject by diminishing his power of self-conscious coördination and direction of effort. He learns to depend upon an extraneous force instead of depending upon himself. The hysteric or moral imbecile frequently shows that his chief deficiency is a susceptibility to every fleeting idea or impulse that may come before the mind. Among others, such ideas or impulses may be suggested to him by the hypnotizer; continued hypnotization makes the victim more susceptible to such influence, and a general susceptibility to the suggestions that come from without takes the place of those that come from a single source. Mental tonic is what such persons need; they need to have suggested to them that they themselves can overcome these difficulties; they need to be taught methods of self-conquest; they need to be made independent of the hypnotizer. Many such cases, like broken reeds, lean upon the personality of the hypnotizer. When that is removed, like broken reeds, they fall to the ground.

PROGRESS IN OPHTHALMOLOGY.

EXTRACTION OF THE CRYSTALLINE LENS IN HIGH DEGREES OF MYOPIA.

The correction of errors of refraction, by means of glasses, has reached, at the present time, a high degree of excellence, conferring its greatest benefits on humanity when applied to far-sighted, astigmatic, and moderately myopic eyes. The extremely near-sighted eye, largely a product of civilization, presents certain features which render it impossible to afford to the possessor the degree of relief that is desired, by the application of correcting glasses. In myopia of 15 diopters, the farthest point of distinct vision is 2.6 inches; the individual is able to see objects with reasonable distinctness at a slightly greater distance, and usually holds whatever he is reading somewhat further from the eye. With a practical far-point at 4 inches, the degree of convergence necessary for binocular vision is excessive, calling for great exertion on the part of the internal recti muscles. It is also necessary for the individual to bring his head close to the object viewed—conditions that tend to augment myopia. Myopia of the higher degrees is often progressive. The globe elongates and, as it becomes enlarged, carries with it such changes as posterior staphyloma, posterior choroidal atrophy, rarification of retina and choroid at the posterior pole, detachment of the retina, spontaneous subluxation of the lens, degeneration of the vitreous, etc., with consequent partial or total loss of vision. A strong concave glass before an eye causes a reduction in the size of the retinal image and lessens, to some extent, the degree of illumination. The effect produced is as though one were looking through the large end of an opera-glass, and is so unpleasant that the patient prefers to wear a glass that falls short of the full correction.

The extraction of the crystalline lens for the

improvement of vision and the alleviation of the condition in high degrees of myopia was first practised, according to M. Dujardin, by the Abbé Desmonceaux, in France, in 1776, but did not come into general use. In 1887, Tukala removed the crystalline lenses in two cases of high myopia, and presented the patients at a meeting of the Vienna Medical Society in 1889. The vision had been greatly improved and the myopia had not progressed. Soon the discussion of the procedure became widespread. Much was said for and against the operation, but its advocates steadily gained ground, until now the benefits conferred on the patients are becoming fully realized, and the operation has reached a position in ophthalmology which it bids fair to retain.

The operation employed by nearly all ophthalmic surgeons is discission; the greater part of the crystalline lens is broken up by means of the discission-needle. In from two to five days, according to the rapidity with which the lens-débris becomes opaque and swollen, the lens-substance is removed through a small, linear, corneal incision, without iridectomy. There are exceptions to this general rule. Although absorption of lens-débris does not go on so rapidly in old as in young individuals, the progress is quite satisfactory, because of the fact that sclerosis of the lens is less marked in myopic eyes. Von Hippel states that sclerosis does not occur in the lens of myopic eyes, but this statement must be somewhat modified.

But few accidents occur when the operation by discission and subsequent evacuation of the lens-débris by linear extraction is resorted to. Pflüge, who has operated in more than eighty cases, believes that the operation is, in a measure, protective, and even curative, as he has observed one recovery. The evidence obtained goes to prove that the accidents that follow the operation are much less numerous than those observed after cataract-operations.

It is very important to know what the effect of the operation is on the myopia. Does it, or does it not, prevent its progress? Fukala has observed cases in which the operation was performed on one eye and not on the other, the condition remaining stationary in the eye operated upon and advancing in the other. Pflüge has observed two cases where the myopia has advanced, establishing the fact that the operation does not arrest the progress of the myopia in all cases.

In regard to the advisability of operating on one or both eyes, operators are largely agreed that if the myopia is of approximately the same degree in both eyes, the lenses should be removed from both. Operation on a single eye is advised only in cases where one eye is much more near-sighted than the other, or where there is and will be no attempt at binocular vision. Fukala urges the double operation in all cases of high myopia in which divergence or convergence is threatened, asserting that binocular vision may be retained after the crystalline lenses are removed.

The effect (Schanz, *Graefe's Arch.*, vol. xii, 1, p. 109) on vision after the operation is truly remarkable; in this all operators are agreed. The gain is usually twofold or threefold, in some cases (Fukala) tenfold. This improvement is made possible by the increase in the size of the image formed on the retina and in the more or less increased illumination. The image, before and after the operation, in myopia of 12 to 14 D. holds the approximate ratio of two to three. The power of accommodation, except in the low degree, possible to some aphacic eyes is done away with; but since the accommodation in high degrees of myopia is employed but little, this is hardly missed by the patient, and does not constitute a serious objection. The patient is enabled to read at a greater distance, can do ordinary work, and, in fact, reaps all the benefits of having a far-point at infinity.

The effect on the refraction differs in the various cases. Fukala records a difference in the refraction before and after the operation of 12.75 D. to 20 D.; Pflüge, 14.5 D. to 20 D.; Pergens, 14.5 D. to 18 D.; Von Hippel, 14 D. to 24 D.; Sattler, 11.50 D. to 20 D. The difference does not seem to bear any relation to the degree of the myopia. By the above it will be seen that the operation practically converts a highly myopic eye into an eye approaching the normal, so far as the refraction is concerned.

It is, of course, difficult to induce a person who

has useful vision to undergo an operation which, to the average layman, is full of the possibilities of disaster. The facts now at hand will enable the surgeon to hold out hopes to the patient of relief from restraint in the use of his eyes, of greatly improved vision, and of arrest of a process that must ultimately result in great impairment of vision. The operative procedure should therefore be much more readily accepted. According to Lawford (meeting of the British Medical Association), one thousand operations for the removal of the lens in high degrees of myopia have already been reported. Many of these operations have been performed in Germany, some in France, a few in England, and almost none in the United States. It is true that high degrees of myopia are met with here much less frequently than in Germany, but the cases in this country that would be benefited by the operative treatment are not a few, and it is to be hoped that they will find the relief this treatment affords.

JOHN E. WEEKS, M.D.

ECHOES AND NEWS.

Opotherapy.—Lardowzy has given the above name to the use of the animal extracts in medicine.

A Clerical Dentist.—A Sunderland (England) vicar has extracted 25,000 teeth from his parishioners in the course of his pastorate.

Sphygmogenin.—Fraenkel has isolated a principle (sphygmogenin) from the suprarenal capsules. Its presence in the blood is believed to cause increased arterial pressure.

Sanitariums for Consumptives.—It is announced that several large insurance companies are figuring on the cost of maintaining sanitariums in the Rocky Mountain regions for the accommodation of their consumptive risks.

Venereal Diseases in India.—The Government of India is quietly renewing its former stringent regulations against venereal diseases. The medical reports declare that three-fourths of the troops in every cantonment are disabled from these diseases.

The Italian Medical Congress.—The seventh Italian Congress of Medicine was held at Rome, October 20th to 24th. Subjects discussed were recent progress in the physiological pathology of the cerebrum and cerebellum, and myocardiac insufficiency.

Oceanic Gold.—Professor Liversidge of Sydney University has made chemical experiments which show that there are over 100,000,000,000 tons of gold dissolved in the ocean-water of the world, basing his calculation on the rate of one grain per ton, which he found in the water on the Australian coast.

Yellow Fever at Hoffman Island.—In accordance with a requirement of the Health Officer, an unacclimated passenger from Havana was taken to Hoffman Island, New York Harbor, October 19th, to pass the incubation-period there. He developed yellow fever the same night, and died two days later.

Leprosy in Germany.—Professor Koch, who passed ten or twelve days in the district of Memel, studying cases of leprosy and their causes, has discovered only one case. He considers the danger of infection less great than is generally supposed, otherwise the disease would have extended more rapidly.

Human Telegony.—An English doctor reports that one of his patients, married to a man with red hair, had no children. He died, and her second husband had black hair, and was otherwise very unlike her first. Several children were born from the second marriage, and all bore a striking resemblance to the first husband and had red hair.

Formic Acid in Rheumatism.—In Russia, peasants affected with rheumatism collect ants' nests in bags, which they plunge into a tub of hot water. This bath has counter-irritant properties, on account of the formic acid given off, and by bathing in it the patient is benefited. On the same principle, Indian tribes treat rheumatism with the sting of bees.

The New York County Society.—At the annual meeting of this Society, held Monday evening, October 26th, the following officers were elected: President, Dr. Landon Carter Gray; vice-presidents, Dr. Robert A. Murray, Dr. Nathan Edward Brill; secretary, Dr. Charles H. Avery; assistant secretary, Dr. William E. Bullard; treasurer, Dr. John S. Warren.

The Charlotte Medical Journal.—We notice great improvements, both in size and appearance, in this popular monthly, and congratulate the editors upon their enterprise. In a State where there does not exist a single medical school, the usefulness of a high-class medical journal cannot be overestimated, and this periodical seems to be meeting the demand in a way to meet the approval of the entire profession.

Southern Section of the American Laryngological Society. The meeting of the Southern Section of the American Laryngological, Rhinological, and Otological Society will be held in New Orleans, March 3 and 4, 1897. This will permit visiting members to see New Orleans during the Carnival season, and will enable them to secure half-rate railroad transportation. A meeting of this Society in the South is a distinctly new enterprise, and should be encouraged.

Phenyl-hydrazin Test for Sugar.—In the *Lancet*, Dr. Mark MacDonald of Liverpool says: "Of all the methods

for determining the presence of small quantities of sugar, by far the most satisfactory, to my mind, is the phenylhydrazin test. This test appears to have gained some by no means merited discredit. This is due not to the test, but to the methods of applying it. Unless one is prepared to spend time and trouble over it, it is better to leave it alone."

The Value of a Fish-diet.—The *Saturday Review* has recently taken up a controversy with some of the British medical journals on the question whether fish is the food for men of genius, and in the course of it declares that "the style and character of Dr. Johnson remained the same, whether he drank lemonade and tea or port and punch." On champagne and ortolans, the writer adds, Burns would have written neither better nor worse than on collops and toddy.

Officers of the New York Obstetrical Society.—At the annual meeting of the New York Obstetrical Society, October 20, 1896, the following officers were elected: President, Dr. R. A. Murray; first vice-president, Dr. C. A. von Ramdohr; second vice-president, Dr. G. W. Jarman; recording secretary, Dr. A. M. Jacobus; assistant recording secretary, Dr. Le Roy Brown; corresponding secretary, Dr. H. J. Boldt; treasurer, Dr. J. Lee Morrill; pathologist, Dr. G. C. Freeborn.

Change of Name.—The editors of *Mathews' Medical Quarterly* announce that with the January issue of that publication its name will be changed to *Mathews' Quarterly Journal of Rectal and Gastro-Intestinal Diseases.* This is a change which has been deemed necessary for some time, as it is essential that the title of a medical journal should convey to the reader an idea of its contents, and this has not been the case with its name from the beginning. It will continue to be the only English publication devoted to diseases and surgery of the rectum and gastro-intestinal tract. The journal will continue to be edited by Drs. J. M. Mathews and Henry E. Tuley, and published in Louisville, Ky.

The Medical Service at St. Paul's.—The unusual success of the doctors' service in St. Paul's Cathedral, London, on the anniversary of St. Luke's Guild, October 21st, is heralded as evidence of a medical rebound from materialism. The Lord Mayor went in state, the representatives of the Royal College of Physicians and Surgeons were met at the door by the Dean of the Cathedral and his staff, and robed medical representatives of the Universities of Oxford and Cambridge, Sweden, Brussels, Heidelberg, Paris, and Berlin, with a party of ladies clad in scarlet robes as doctors of medicine, made an imposing procession. Out of 5500 doctors in London, 1000 attended and listened to the Bishop of Stepney's plea for harmony between science and religion.

Vital Statistics from Damascus.—The Bureau of Statistics of Paris induced the French Government to exchange statistical matters with the Turkish Government. Both Governments consented, and the French Bureau of Statistics prepared blanks to be filled out, which were handed by the French Ambassador to the Turkish authorities. The Parisian bureau has sent six blanks. The questions to be answered were the following: "What is the death-rate of the city? 2. What is the rate of births? 3. How is the supply of drinking-water? 4. How much goods are imported? 5. How much goods are exported? 6. General remarks pertaining to the welfare and health of the people." One blank came back filled out by the chief magistrate of the city of Damascus. The blank read thus: "Answer to 1. In Damascus everyone must die at the command of Allah. Some die young, some die old, but everyone must die. 2. I cannot answer this question. Allah alone knows that. 3. Since time immemorial nobody died of want of water in the city of Damascus. 4. and 5. I never cared of my neighbor's business, and I cannot say how many camel-loads are brought to or sent from Damascus. 6. Since Allah has sent his prophet, Mohammed, into this world, who has cleansed the world with fire and sword, things are a little better, but there is much to be done yet, and much room for improvement. And now, my sweet lamb, do not ask any more such questions, which are neither good for you nor anybody else. This is the first and last blank I filled out for you.—Selam Aleikam."

Relation of Mental Shock to the General Health.—Sir Benjamin W. Richardson, M.D., in *Longman's Magazine*, gives an instance of the effects of mental shock in causing permanent bad health, mental and other—effects that are all too easily inflicted in early life, whether in the period of infancy or in that of school-life. The following is an instance drawn from the latter period: A gentleman who, for many years, was under his observation as a confirmed mental invalid, a strong man in many respects, but utterly irresolute, and, in the end, of disordered mind altogether, acquired his mental disease from sudden distrust. He had, in his childhood, an innate dread of deep water, and he had, at the same time, a tutor for whom he held the warmest affection, coupled with the most absolute trust and confidence. In a thoughtless and unhappy moment this tutor became possessed with the idea that he would break his pupil's dread of deep water by pitching him into a pool where they were accustomed to bathe together, at the deepest part. There was no actual danger, for the depth was really not great, the pool was calm, the boy could swim a little, and in an instant the tutor, a strong and skilful swimmer, was in the water himself, rendering succor and support. The lad was brought to shore safely enough, but the mischief to the mind was inflicted beyond repair. His confidence was obliterated, and a fixed distrust in the mind of the youth was set up forever. If a skilful physiologist could have discovered the seat of trust in that youth and could have destroyed it mechanically, he could not have inflicted a more severe injury nor one more determinately lifelong in its effects.

The Pan-American Medical Congress.—Dr. H. L. E. Johnson announces the following transportation-rates for the meeting of the second Pan-American Medical Congress, to be held in the city of Mexico, Mexico, on No-

vember 16 to 19 inclusive, 1896: The New England roads have made no reduction at all in rates, and the trunk lines have made no general reduction, but have agreed to special rates from the points mentioned in their territory, *viz.*: From New York City to city of Mexico and return, $78.50; from Philadelphia and return, $76.00; from Baltimore and return, $73.50; from Washington and return, $71.50. Should the delegates desire to enter Mexico by one gateway, say Eagle Pass, and return via another gateway, either Laredo or El Paso, an additional charge of $5.75 total will secure such privilege. Pullman berths will cost $23.00 each way. Delegates residing in central traffic-territory, embracing the territory from Buffalo, Pittsburg, and Parkersburg, W. Va., in the East, to Chicago and St. Louis, in the West, will be accorded a round-trip ticket to city of Mexico over any of the lines, on the payment of one first-class fare. Delegates residing in the Western traffic-territory will obtain the round-trip ticket to the city of Mexico for one fare, over the following roads *only:* Missouri Pacific; Illinois Central; Wabash; Chicago & Alton; Atchison, Topeka & Santa Fé; Chicago, Rock Island & Pacific; Chicago Great Western, and Burlington, Cedar Rapids & Northern Ry. Delegates residing in Southern Pacific traffic-territory will be accorded the one-fare rate to the city of Mexico and return. The three Mexican lines have accorded the round trip for one first-class fare. The fare over the Ward Line for the round trip from New York to the city of Mexico, via Tampico, has been reduced, and for this occasion will be $78.00, including meals and stateroom. Special service is arranged for with the American Tourist Association of Chicago, who will provide a special train of sleeping- and dining-cars to run through from Chicago, Cincinnati, and St. Louis to the city of Mexico and return, connecting with the B. & O. R. R. trains from points east and north. This will be the official train and route, and will leave Chicago, Cincinnati, and St. Louis November 10th.

SELECTION.

THE DISCOVERY OF ANESTHESIA AND ITS ADOPTION IN GREAT BRITAIN.[1]

THE "WINE OF THE CONDEMNED" IN ANTIQUITY.

THE idea of blunting the sensibility by artificial means, in order to lessen the pain caused by the knife and the cautery, is almost as old as surgery. The ancient Egyptians are believed to have used Indian hemp and poppy-juice for the purpose, and the *φάρμακον νηπενθὲς*, the sorrow-easing drug, which, we are told in the fourth book of the "Odyssey," was given by Helena to Ulysses and his comrades, may have contained these substances; at any rate, it is expressly stated that she had learned its composition from Polydamnia, the wife of Thone, in Egypt. The "wine of the condemned," referred to by the prophet Amos (ii. 8), is conjectured by Simpson to have been a preparation of cannabis indica. Whatever it was, it in all probability was a narcotic potion of some kind. The Jews were more humane in their method of dealing with condemned criminals than the Greeks or the Romans. In the Talmudic writings there are several passages which seem to show that it was the practise to ease the pain of torture and death by stupefying the sufferers. Thus: "If a man is led forth to death, he is given a cup of spiced wine to drink, whereby his soul is wrapped in night;" and again: "Give a stupefying drink to him that loseth his life, and wine to those that carry bitterness in their hearts." According to tradition, while the Roman conqueror held sway in Palestine, and crucifixion was a common punishment of malefactors, the Jewish women, with the sanction of the Sanhedrin, were wont to ease the death-agony of the sufferers by giving them something in the nature of a "wine of the condemned" upon a sponge. It is probable that the "wine mingled with myrrh," which, according to St. Mark (xv. 23), was offered to Christ while he was hanging on the cross, was a narcotic draft intended to make death painless. In China it is well known that opium is used to the present day, and executioners are often bribed to allow it to be administered before they begin their cruel work.

The Greeks also used means to deaden sensibility to pain. Pindar tells us that Machaon eased the sufferings of Philoctetes with a narcotic potion. Theocritus speaks of Lucina, the goddess whose specialty was the obstetric art, pouring an insensibility to pain down all the limbs of a woman in labor. Unfortunately no details are given of the method adopted. The narcotic properties of mandragora (*Atropa mandragora*, L.), which is allied to our *Atropa belladonna*, or deadly night-shade, appear, however, to have been known to the Greeks, and various preparations of that plant were in use as anesthetics among the Romans. The younger Pliny (A.D. 32–79), in his "Natural History," says that a decoction of it was used by way of preparation for surgical treatment: "Bibitur contra serpentes et ante sectones punctionesque ne sentiantur." The agent was sometimes inhaled, as is clear from Pliny's remark that in some cases sleep may be induced by the smell. Dioscorides (circ. 50 A.D.) gives several prescriptions for the use of the drug for the same purpose. One of these, as quoted by Simpson, is as follows:

"Some persons boil the root in wine down to a third part and preserve the decoction, of which they administer a cyathus in want of sleep and severe pains of any part, and also before operations with the knife or the actual cautery that they may not be felt."

Of a special variety of the plant which was called *μώριον*, probably because it engendered *μωρία*, or foolishness, in those that partook of it, the same author speaks as follows:

"They relate that a dram of it being taken as a draft, or eaten in a cake or other food, causes infatuation and takes away the use of the reason. The person sleeps without sense in the attitude in which he ate it for three or four hours afterward. Medical men also use it when they have recourse to cutting or burning."

Atropa mandragora grows in the Grecian Archipelago, and Sir Benjamin Ward Richardson says that many years ago he received some specimens from the late Mr.

[1] From *The British Medical Journal.*

Daniel Hanbury, who had collected them while traveling in Greece. Sir Benjamin prepared a draft of mandragora according to the prescription of Dioscorides. He says that "the phenomena repeated themselves with all faithfulness," and he adds that "there can be no doubt that in the absence of our now more convenient class of anesthetics, morion[1] might still be used for general anesthesia." Seneca, Apuleius Lucius, and other ancient authors also refer to the narcotic effects of mandragora. From a casual reference made by the theological writer Origen to a draft which cast patients, when surgical operations are to be performed, into a deep sleep, the practise of inducing anesthesia would appear to have been common in the third century. The drug used was doubtless mandragora. In the same century Indian hemp was employed for the same purpose in China.

In a collection of old Chinese writings, entitled Kou-Kin-I-Tong, presented many years ago to the French Academy by M. Stanislas Julien, there is a biographical sketch of a surgeon named Moa-Tho, who, in the years 220–230 of our era, gave patients on whom he wished to perform painful operations a substance called Ma-Yo, which is said to have been Indian hemp, the effect of which was that after a few moments they became insensible, as if they were drunk or deprived of life.

A local anesthetic agent is referred to by Pliny and Dioscorides as *lapis Memphiticus*, or Memphis stone. This, powdered and mixed with vinegar, was applied to parts which were to be cut or burned. Littré conjectures that this stone was a kind of marble which, on the addition of vinegar, gave off carbonic acid, which deadened the sensibility of the nerve-ends. Withington suggests that it may have been a kind of bitumen, and that such anesthetic effect as it may have had was due to the phenol which it contained.

THE "DROWSY SIRUPS" OF THE MIDDLE AGES.

Down to the sixteenth century, mandragora was in more or less general use as an anesthetic. The most celebrated prescription for its use was that given in the "Chirurgiæ" of Theodoricus of Lucca, Bishop of Cervia (lib. 4, cap. viii.), under the name of "Spongia Somnifera." Theodoricus, who died in 1298, was the son of the famous surgeon Hugo of Lucca, and was himself at the beginning of his career a surgeon. On entering the Church he published the secrets which he had learned from his father. The following is the composition of the "sleeping sponge:"

"Take of opium, of the juice of the unripe mulberry, of hyoscyamus, of the juice of hemlock, of the juice of the leaves of mandragora, of the juice of the woody ivy, of the juice of the forest mulberry, of the seeds of lettuce, of the seeds of the dock which has large round apples, and of the water hemlock—each an ounce; mix all these in a brazen vessel, and then place it in a new sponge; let the whole boil as long as the sun lasts on the dog-days until the sponge consumes it all, and it has boiled away in it. . . . As oft as there shall be need of it place this sponge in hot water for an hour and let it be applied to the nostrils of him who is to be operated on until he has fallen asleep, and so let the surgery be performed."

After the operation the patient was to be aroused in the following manner:

"This being finished, in order to awaken him, apply another sponge dipped in vinegar frequently to the nose, or throw the juice of the root of fenugreek into the nostrils; shortly he awakens."

The "Confectio Soporis Secundum Dominum Hugonem" was still in use in the sixteenth century as we learn from Jean Canappe, whose work, "Le Guidon pour les Barbiers et les Chirurgiens," was published in 1538. The concluding sentence of the following passage shows that opium was also used as an anesthetic in his day:

"Aucuns, dit-il, comme Theodoric, leur donnent médicines obdormifères qui les endorment, afin que ne sentent incision, comme opium, succus morellæ, hyoscyami, mandragoræ, circutæ, lactucæ, et plongent dedans esponge et la laissent seicher au soleil, et quand il est necessité, ilz mettent cette esponge en eaue chaulde, et leurs donnent à odorer tant qu'ilz prennant sommeil et s'endorment; et quand ilz sont endormis, ilz font l'opération: et puis avec une autre esponge baignée en vin aigre et appliquée ès narilles les esveillent, ou ilz mettent ès narilles ou en l'oreille, succum rutæ ou feni, et ainsi les esveillent, comme ilz dient. Les autre donnent opium à boire, et font mal, spécialement s'il est jeune, et le apercoivent car ce est avec une grande bataille de vertu animale et naturelle. J'ai ouï qu'ilz encourent manie et par conséquent la mort."

Dr. E. T. Withington, in his "Medical History from the Earliest Times," quotes the following recipe from the author of the "Breviarium" (Arnald of Villanova?):

"*To produce sleep so profound that the patient may be cut and will feel nothing, as though he were dead.* It is an 'experimentum' of Magister Michael Scot. Take of opium, mandragora-bark, and henbane-root, equal parts, pound them together, and mix with water. When you want to sew or cut a man, dip a rag in this and put it to his forehead and nostrils. He will soon sleep so deeply that you may do what you will. To wake him up, dip the rag in strong vinegar. The same is excellent in brain-fever, when the patient cannot sleep, for if he do not sleep he will die."

A somewhat similar prescription is given by Nicholas, provost of the famous old medical school of Salerno, in his "Antidotarium."

The idea of anesthesia produced by drugs was familiar to medieval romance-writers and poets. In Boccaccio's "Decameron" the catastrophe of one of the stories turns on a gallant drinking by mistake a draft prepared by a surgeon for a patient whose leg he was about to amputate. Marco Polo tells us that the Old Man of the Mountain used to drug his victims. Du Bartas, in the sixteenth century, wrote (as Englished by Silvester):

> Even as a surgeon, minding off to cut
> Some cureless limb, before in use he put
> His violent engines on the vicious member,
> Bringeth his patient in a senseless slumber,

[1] Sir Benjamin uses the word "morion" as denoting the potion itself rather than the particular kind of mandragora from which it was made. He further translates "morion" as "death-wine," as if it had something to do with the Latin *mori*, an etymology which, as Count Smorltork might have said, "surprise by himself."

> And griefless then (guided by use and art)
> To save the whole cuts off th' infected part.

Shakespeare's allusions to poppy, mandragora, and other "drowsy sirups," are too familiar to need quotation, but the following passage from a somewhat later dramatist is interesting. Middleton, in a play called "Women, Beware Women," writes:

> I'll imitate the pities of old surgeons
> To this lost limb, who, ere they show their art,
> Cast one asleep, then cut the diseased part.

In the days of the rack and the thumbscrew it was natural that there should be traditional secrets among criminals for baffling their tormentors. The following passage is quoted by Simpson from "Le Procès Criminel" of Claude Lebrun de la Rochette:

"As to their artifices not to feel the pain of the rack, I saw in the first year of my reception at the bar of Beaujolais, which was in the year 1588, that one of four thieves who were prisoners, the chief named Grand François, a man of gigantic stature, was put to the rack, fell asleep, and the toes were torn from both his feet, without his manifesting any signs of pain. One of his companions observed that he had eaten soap, which stupefied the nerves. The remedy to the artifice is to give wine, which being brought and drunk, he then said he was dead, and without further torture freely confessed an infinite number of murders and robberies."

From other writers of the same period it may be gathered that soap dissolved in clear water was believed by the poor wretches, who went in fear of the attentions of the ministers of the law, to have the power of making them insensible to torture.

Local anesthesia was not unknown. Besides the Memphis stone already referred to, we read of inunctions of opium, celandine, saffron, the marrow and fat of a man, with the oil of lizards, as likely to help a person on the rack in withholding the confession it was desired to extract from him. Bernard states that the Salernitans used to rub up poppy-seed and henbane and apply them as a plaster to deaden sensibility to parts to be cauterized.

Local anesthesia was sometimes produced by freezing, as is shown by the following passage from Thomas Bartholinus:

"Antiqua cauterio ulcera in membris excitentur; nix affricata induit stuporem. Id me docuit Marcus Aurelius Severinus in Gymnasio Neopolitano olim præceptor meus et hospes, Chirurgorum hoc sæculo princeps. Rectissime autem nivem in vasculum materiæ convenientis capax, sed oblongâ ad extremum et myrtiformi specie, conjectam, sine rei ullius interventu applicavit. A gangrænæ metu securos nos jussit, medicamento sub angustis parallelis lineis applicato, sensu vero post horæ quadrantem sopito, secare locum indolentum licebit."

About the end of the sixteenth century the belief in mandragora and other substances so long credited with anesthetic properties seems to have died out rather suddenly. Ambroise Paré speaks of the "spongia somnifera" as "used formerly" by operators. Simpson conjectures that it was found too dangerous; Snow, however, expressed his "utter disbelief that a sponge containing the oil prepared as above, would, after being placed in hot water, give off any odor or vapor that would cause insensibility." However that may be, we do not hear much of anesthetic drafts or inhalations till near the end of the century. In 1782, Weiss, a pupil of J. L. Petit, is said to have operated on the foot of Augustus, King of Poland, while the royal patient was under the influence of "a certain potion surreptitiously administered."

Other means of producing insensibility were tried and one after the other found wanting. Compression of the carotid arteries, which, according to Casper Hoffmann, used to be practised by the Assyrians of old in the circumcision of boys, was employed by Valverdi and others in the sixteenth and seventeenth centuries. Morgagni used this method in vivisection of animals, and suggests that it might be used on human beings. Surgeons have, however, left this mode of producing anesthesia to garoters, who found it very successful for the particular purpose they had in view. Compression of the nerves supplying the limb to be removed was proposed by James Moore in 1784, and was tried with no very brilliant success by Hunter, Malgaigne, and others. Three years before, Sassard, surgeon to the Charité of Paris, had recommended that patients should be prepared for the knife by free drugging with narcotics as a means of preventing shock. In 1800, Humphry Davy in experimenting with nitrous oxid gas found that it relieved pain. To quote his own words:

"The power of the immediate operation of the gas in removing intense physical pain I had a very good opportunity of ascertaining. In cutting one of the unlucky teeth called *dentes sapientiæ*, I experienced an extensive inflammation of the gum, accompanied with great pain, which equally destroyed the power of repose and of consistent action. On the day when the inflammation was most troublesome I breathed three large doses of nitrous oxid. The pain always diminished after the first four or five inspirations, the thrilling came on as usual, and uneasiness was for a few minutes swallowed up in pleasure. As the former state of mind, however, returned, the state of organ returned with it."

In the following passage Davy clearly points out the anesthetic properties of the gas and the use to which they might be put by surgeons:

"As nitrous oxid in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place."

The anesthetic effects of ether were also plainly enough shown by the case of Lady Martin, reported by Sir Thomas Watson in his classical "Lectures on the Principles and Practise of Physic:"

"Long before its power was used to prevent the inflicted pain of surgical operations, the vapor of ether had been successfully employed to suppress the inbred sufferings of natural disease. A former patient of mine told me this story of herself. She had been sorely tried, in her earlier years, with paroxysms of urgent dyspnea,

frequently recurring, and her life was thought to be in danger. After fruitless trials of various other remedies, the following method was adopted, with the happiest result, under the advice of a physician of high promise, who died young, the late Dr. Woolcombe of Plymouth.

"About two teaspoonfuls of sulphuric ether were poured into a saucer, which was placed on her lap, and over which she breathed, as she sat gasping in bed, with a shawl thrown over her head to prevent the escape of the vapor. Very soon a delightful sensation of tranquility ensued; she felt (I quote her own words) 'as if going to heaven in a most heavenly way;' and presently she sank back unconscious. As soon as this happened, her husband (the late distinguished Admiral of the Fleet, Sir T. Byam Martin), by whom the process was managed, withdrew the shawl, and in a short time Lady Martin gradually recovered, breathing calmly."

"This mode of quieting her attacks of asthma was begun in 1806, a few years after the publication of Sir Humphry Davy's hint; and it was repeated again and again, sometimes twice in the same day, for a very considerable period. Lady Martin survived the prediction of her speedy death for forty-three years."

But the teaching of this case and the more explicit statement of Humphry Davy were overlooked, and both nitrous oxid and ether remained little more than scientific playthings, which were used by professors of chemistry to relieve the tedium of their prelections. Meanwhile the operating-theater continued to be a place of hideous torture, and surgeons were often too glad to take advantage of any means of escape from the necessity of using the knife.

THE ADVENT OF TRUE ANESTHESIA.

So far the history of the efforts to free surgery from the black shadow of pain which darkened its footsteps had been a record of delusion and failure. Surgeons had given up hope of finding any means of masking the terrors of the knife, and Valpeau had declared that "the prevention of pain in operations is a chimera which it is not permitted to pursue." Yet the words had scarcely been written when the problem which so long had been the "mere despair of surgery," and which had just been pronounced on such high authority to be insoluble, was triumphantly solved. This great step in the progress of mankind we owe to America. To a young dentist of Hartford, Conn., belongs the credit of having practically proved for the first time the possibility of abolishing sensation so utterly that a painful operation could be done without being felt.[1]

ORIGIN OF THE TERM ANESTHESIA.

The proper naming of a new substance or a new process is often almost as troublesome as the discovery of it. Soon after the memorable 16th of October a meeting was held at the house of Dr. A. A. Gould, in Boston, to choose a name for the last heir of Morton's invention. At this meeting were present Dr. Henry J. Bigelow, Dr. O. W. Holmes, and Dr. Morton, and Dr. Gould read aloud a list of names which he had prepared. On hearing the word "Letheon" Dr. Morton exclaimed, "That is the name the discovery shall be christened." Dr. Gould and others also favored this name, which is derived, of course, from Lethe, the river of forgetfulness. Subsequently, however, Dr. Holmes wrote a letter to Dr. Morton in which he proposed the name which has since come into general use.

THE FIRST OPERATION UNDER AN ANESTHETIC IN ENGLAND.

The first operation under ether in this country was performed by Robert Liston in University College Hospital on December 22, 1846. Among those present on the occasion were the late Sir John Erichsen, Sir Joseph Lister, Mr. William Cadge of Norwich, Dr. W. H. Ransom of Nottingham, and Dr. William Squire.[1] Mr. William Cadge has been good enough to send us the following interesting note on the subject:

"I have no written notes of what took place on that memorable occasion, and I must trust to my memory, which may betray me into mistakes as to some minor details, but as to the main incident of amputation of the thigh, the scene was too startling and dramatic ever to be erased from my recollection.

"Dr. Boot of Gower street had reported to Mr. Liston the definite and authentic information of the effect of ether-inhalation that he received from Dr. Bigelow of Boston in December, 1846. Two days after this communication was the operating-day at University College Hospital, and Liston resolved to put the matter to the test. In the interval, Mr. Squire, the well-known chemist of Oxford street, prepared the apparatus, and Mr. (now Dr.) Squire administered the ether.

"On December 21, 1846, at two o'clock, the operating theater was filled with students and spectators; Liston addressed a few words to them as to the nature of the experiment about to be tried, and it was manifest that he had but faint hopes of its success.

"The patient was a man rather below middle age who, to the best of my recollection, had malignant disease of the skin and tissues of the calf of the leg, for which amputation of the thigh was deemed to be necessary. He was a man of courage and of intelligence above the average of hospital patients, and he expressed his willingness to try the inhalation of ether. The apparatus comprised a large bell-shaped glass reservoir containing ether, and a long tube and mouth-piece. Fortunately the vapor caused no bronchial irritation or nervous excitement; the patient passed easily into complete insensibility, and Liston removed the thigh as rapidly as possible; a gentleman present, watch in hand, declared that the cutting operation lasted thirty-two seconds only. It was done by the antero-posterior flap-method; the femoral artery was con-

[1] The discovery of the anesthetic influence of nitrous oxid in 1844 by Horace Wells, who is referred to above, his public failure to demonstrate its value in the surgical amphitheater of the Massachusetts General Hospital, and the subsequent success of ether in the hands of his associate Dr. W. T. G. Morton in the same place on October 16, 1846, are facts in the early history of anesthesia in the United States so well known by every American that we shall economize space by omitting an extended treatment of them at this point.—[Ed.]

[1] See Dr. Squire's own account on a subsequent page.—[Ed.]

trolled by finger-pressure; only three or four vessels required a ligature; lint dipped in water was placed between the flaps, and the stump was folded in a towel and all signs of blood cleared away.[1]

"In a few minutes the patient woke up completely, and could answer these questions: 'Did he feel able to undergo the pain of the operation?' 'Yes, he would submit as best he could.' 'Did he not know that the limb was off?' Then he remonstrated against trifling with his feelings at such a moment; but, when the towel was removed from the uplifted stump so that he could see it, he burst into tears and fell back on his pillow.

"The scene at this moment was most impressive, for the success of the whole proceeding was as complete as could be witnessed at the present time. The great surgeon was almost as much affected as the patient; he saw at a glance what a blessing was in store for the human race, and what a boon for the surgeon, and he could scarcely command himself sufficiently to address even a few words to the spectators.

"The next case did not go off so smoothly. The patient was a rough fellow with an ingrowing toe-nail. He became boisterous and violent under the inhalation; he thrust the assistants on one side, jumped off the table, and, so far as I remember, escaped from the theater. He must, however, have been restrained or brought back and rendered insensible, seeing that the necessary operation was done without pain.

"Liston for that day could think of nothing but this wonderful discovery. He wrote this short note to Dr. Boot: '5 Clifford street, December 21, 1846. Dear Sir,—I tried the ether-inhalation to-day in a case of amputation of the thigh, and in another requiring evulsion of both sides of the great toe-nail, and with the most perfect and satisfactory results. It is a very great matter to be able thus to destroy sensibility to such an extent without apparently any bad result. It is a fine thing for operating surgeons, and I thank you most sincerely for the early information you were so kind as to give me of it. Yours faithfully, Rob. Liston.' He also wrote a characteristic letter to his old friend and former assistant, Professor Miller of Edinburgh. I think the letter found its way into a Scotch newspaper, but I can only remember that it began and ended with a quotation from St. Paul, 'Rejoice, and again I say rejoice.'

"That evening I dined with Mr. Liston (I was acting as his private assistant at the time). Two ladies were present, and after the cloth was removed nothing would content him short of my exhibiting the effects of ether by inhalation. When about half under its full effect I could just hear the elder lady say, 'Liston, for God's sake stop; you will be the death of that poor young man.' He did stop, but I felt the effect of his strong grip of the lobe of the ear for a day or two."

CHLOROFORM.

To no man in this country was the announcement that a means of inducing anesthesia had been discovered more welcome than to Dr. James Young Simpson, at that time Professor of Midwifery in the University of Edinburgh. As his daughter, Miss Eve Blantyre Simpson, relates in the most interesting "Life" of her distinguished father, with advance-sheets of which we have been favored,[1] "very early in his student days he had been so sickened at the suffering he witnessed in the operating-theater that he had shrunk from the scene, decided to abandon his medical studies, and seek his way in the paths of the law." Happily for mankind—and particularly for womankind—he did not carry out this determination. As soon as he heard of the use that was being made of ether for surgical purposes in America, he tried it in midwifery. This was on January 19, 1847, and Simpson was the first to use the anesthetic for the relief of the pains of labor. Finding, however, after a time, to quote his own words, that "no busy obstetric practitioner could extensively employ sulphuric ether without inevitably carrying about with him, and upon his clothes, an odor so disagreeable to many other patients, and other houses, as to make his presence there aught but desirable," he set himself to discover something better than ether. Speaking of this search he said:

"Latterly, in order to avoid if possible some of the inconveniences pertaining to sulphuric ether, particularly its disagreeable and persistent smell, its occasional tendency to irritation of the bronchi during its first inspirations, and the large quantity of it required to be used (more especially in protracted cases of labor), I have tried upon myself and others the inhalation of different other volatile fluids, with the hope that some one of them might be found to possess the advantages of ether without its disadvantages. For this purpose I selected for experiment and have inhaled several chemical liquids of a more fragrant or agreeable odor such as chlorid of hydrocarbon, etc. Then Mr. Waldie, a Linlithgowshire man, first named perchlorid of formyl as worthy among others of a trial.

Dr. Jacob Bigelow of Boston and Mr. Jacob Bell, a well-known London pharmacist, had both previously tried chloric ether, and Mr. Bell's experiments had been so successful that Mr. Lawrence used it in surgical operations. Bell, however, failed to recognize that it was the chloroform in the chloric ether that produced insensibility. Mr. David Waldie, who was connected with the Apothecaries' Company at Liverpool, seems to have guessed that chloroform was the active agent, and he promised to procure some for Simpson. There was some delay in carrying the promise into effect, however, and in the meantime Simpson, who was not a man to let the grass grow under his feet, got some chloroform from Messrs. Duncan and Flockhart of Edinburgh, and at once began to experiment with it on himself and his assistants, Dr. George Keith and the late Dr. Matthews Duncan and others. The first trial of chloroform was made in Simpson's house on No-

[1] This was Liston's usual method of amputation. It was the duty of the house-surgeon in the evening, after full reaction from shock, to remove the lint, tie any bleeding points if necessary, and close the flaps with a few points of suture and isinglass-plaster.

[1] The book will shortly be published as one of the "Famous Scots Series," now being issued by Messrs. Oliphant, Anderson, & Ferrier of Edinburgh and London. We have much pleasure in acknowledging the courtesy of the publishers, and of the editor of the series (Mr. Oliphant Smeaton) in the matter.

vember 4, 1847. Miss Simpson quotes the following passage from a letter written by her father to Mr. Waldie, who had drawn his attention to chloroform:

"I am sure you will be delighted to see part of the good results of our hasty conversation. I had the chloroform for several days in the house before trying it, as after seeing it such a heavy unvolatile-like liquid, I despaired of it, and went on dreaming about others. The first night we took it Dr. Duncan, Dr. Keith, and I, all tried it simultaneously, and were all 'under the table' in a minute or two."

Miss Simpson also quotes the following passage from a letter written to her by Dr. George Keith in 1891:

"Dr. Miller, in the appendix to his work on surgery, published soon after, gives a full account of the scene. It is pretty correct, only he says we all took the chloroform at once. This, with a new substance to try, would have been foolish, and the fact is, I began to inhale it a few minutes before the others. On seeing the effect on me, and hearing my approval before I went quite over, they both took a dose, and I believe we were all more or less 'under the table,' much to the alarm of your mother, who was present."

FAR STRONGER AND BETTER THAN ETHER.

Miss Simpson adds that Professor Miller, who was their neighbor, used to come every morning to see if the experimenters had survived. The following passage, which embodies Professor Miller's account of the proceedings, will doubtless be read with interest:

"These experiments were performed after the long day's toil was over, at late night or early morn, and when the greater part of mankind were soundly anesthetized in the arms of common sleep. He describes how, after a 'weary day's labor,' the two sat down and inhaled various drugs out of tumblers, as was their custom, and chloroform was searched for and found beneath a heap of waste-paper, and with each tumbler newly charged the inhalers resumed their occupation. . . . A moment more, then all was quiet; then a crash. On awakening, Dr. Simpson's first perception was mental. 'This is far stronger and better than ether,' said he to himself. His second was to note that he was prostrate on the floor, and that among the friends about him there was both confusion and alarm. Of his assistants, Dr. Duncan he saw snoring heavily, and Dr. Keith kicking violently at the table about him. They made several more trials of it on that eventful evening, and were so satisfied with the results, that the festivities of the evening did not terminate to a late hour, three A.M."

On November 10, 1847, Simpson communicated his discovery to the Medico-Chirurgical Society of Edinburgh in a paper entitled "Notice of a New Anesthetic Agent as a Substitute for Sulphuric Ether." On November 15, 1847, chloroform was used for the first time in a surgical operation in the Edinburgh Royal Infirmary. A public trial of the new agent had been proposed for a previous date, but fortunately for the future of chloroform Simpson could not be found in time to give it, and the patient was operated on without an anesthetic. The case was one of strangulated hernia, and the operator, Professor Miller, had only proceeded the length of dividing the skin when the patient fainted and died with the operation unfinished.

As Simpson himself says: "If the chloroform had happened to be used and this fatal syncope had occurred while the patient was under its action, the whole career of the new anesthetic would have been at once arrested." On the first occasion of its use, three patients were operated on successfully under its influence. One of them (a soldier) was so pleased with the new elixir of oblivion that on awaking after the operation "he seized the sponge with which administration had been made and, thrusting it into his mouth, again resumed inhalation more vigorously than before, as if it were too good a thing to be stopped so soon." At this first public trial of the new anesthetic Dumas, the great French chemist, who had first definitely determined the composition of chloroform, was present, "and was in no small degree rejoiced to witness the wonderful physiological effects of a substance with whose chemical history his own name was so intimately connected."

OPPOSITION TO ITS USE.

Strange to say, the introduction of chloroform met with great and even violent opposition in many quarters. It was not received with enthusiasm by the profession. Surgeons probably were inclined to look askance at a thing which came to them from an obstetrician. Moreover, it was a prevalent belief among them that the pain of an operation was a useful stimulant to the patient. On this ground, as we learn from Sir William Priestley (whose authority we have for citing him as the author of an excellent account of the beginnings of chloroform, which appeared in Dicken's *Household Words* on February 12, 1859), the chief of the Army Medical Staff recommended the surgeons during the Crimean army not to use chloroform. Fanatical clergymen denounced its use in labor as an impious attempt to evade the curse pronounced by the Almighty on Eve and all her daughters. Simpson fought these men with their own weapons, pointing out that the first operation under an anesthetic had been performed by God himself when he cast Adam into a deep sleep before removing his rib. The "scientific" objectors he met with a wealth of convincing argument reinforced by statistics which bore down all opposition. The fight was an obstinate one, but Simpson was victorious, and chloroform won the place, which it held for many years, as the anesthetic most widely used in this country. Its triumph was greatly helped by the courageous example of Queen Victoria, who submitted to be anesthetized at the birth of the late Duke of Albany and at that of Princess Henry of Battenberg. Dr. Snow was the administrator on each of these occasions. On the former of them the inhalation lasted fifty-three minutes. The chloroform was given on a handkerchief in 15-minim doses, and the Queen expressed herself as greatly relieved by the administration. Dr. Snow said that Her Majesty was a model patient.

A LADY'S RETROSPECT.

We have been favored with the following interesting

reminiscences from the wife of a distinguished physician, who was well acquainted with Sir James Simpson:

"I remember one evening entering my mother's drawing-room and finding the professor in the midst of a group of girls all lost in slumber, some just going under the heavenly influence, others coming round. The room reeked with the smell of chloroform. Presently I subsided into the corner of a sofa, and seeing a suspicious-looking handkerchief by my side took it up, found it soaking with something, smelled it, inhaled it, and soon went 'glittering through a dream of things that were.' I knew no more till I came round to a consciousness of the lights in the chandelier above, and of the professor flitting about in great glee calling everybody 'dear.'"

ANESTHETICS AND EXPERIMENTS ON ANIMALS.

It has recently been stated[1] that as regards the "instauration of anesthesia" "there is no suspicion of any experiment on a lower animal in connection with it." This is not the case. Experiments on animals were made by Morton, by Snow, and by Simpson. Simpson's life was, in all probability, saved by an experiment on animals. Lord Playfair speaking in the debate on vivisection in the House of Commons in 1883, related how Simpson in his search for an ideal anesthetic came to his laboratory. A new liquid was put in his hand, and Simpson wanted to inhale it there and then. Playfair, however, insisted on first trying it on two rabbits, which speedily died. Simpson, like Morton, was a reckless experimenter on himself. Miss Simpson tells us that he was once found insensible in his room by his servant Clarke, who said, "He'll kill himsel' yet wi' thae expeeriments, and he's a big fule, for they'll never find onything better than chlory."

THE WORK AND THE WORKERS.

To sum up the story of anesthesia: Nitrous oxid, for surgical purposes, was discovered by Horace Wells; ether we owe to William Thomas Green Morton; chloroform to James Young Simpson. Among these, the largest share of glory may fairly be allowed to Morton, of whom we may say, with Dr. Jacob Bigelow, that "as far as we know he was the only man without whom inhalation might have remained unknown to the present day." To Simpson, however, unquestionably belongs the merit of having made anesthesia triumph over all opposition. For this he deserved the rewards which fell to him in the evening of his days, and the motto which he chose when he was made a baronet, *Victo Dolore*, is the expression of a truth, and not an empty boast.

The First Operation Under Ether in Great Britain.

BY WILLIAM SQUIRE, M.D., F.R.C.P.

Looking back fifty years to the induction of anesthesia by the inhalation of ether-vapor during surgical operations, my own share in securing the early success and general adoption of this method seems to me greater now than it did at one time. With the first announcement from America no details of the mode of administration were received, and failure at the outset would have brought discredit on the discovery, and might have delayed indefinitely the benefit it offered. Several circumstances combined in producing the successful result attained. I had come up to University College in October, 1846, after two or three years' pupilage with an old student of the college, bringing introductions to Quain and Liston, together with specimens of bony union in fractured neck of the femur now in the College of Surgeons. I had assisted Robert Ceely in his experimental transfer of variola into vaccinia, and had gained an interest in surgery from my teacher at Chesham, and from Aston Key at Hemel Hempstead.

Liston, a friend of my uncle the chemist, drew my attention to some cases in his wards, and especially to a delicate fair-haired man, worn out with suppurating knee-joint disease and loss of sleep from the "jerks" caused by eroded cartilage; the man from weakness and fear had more than once refused his consent to amputation. On Saturday, December 20th, I think, Liston came early to the hospital with news of Morton's discovery; he took me with some ether from the hospital to the house of Dr. Boot, and then to Mr. Robinson's opposite; but little ether had been used in the case of the lady who had first submitted to the dentist's hands, whether on that or the previous day I cannot say, but the second case of tooth-extraction at the dentist's house was a failure, not from want of a supply of ether but from want of efficient means of giving sufficient to prevent or overcome the excitement it occasioned. To risk such failure at the hospital, or a repetition of the O'Key's mesmeric deceptions, then of recent notoriety, was out of the question, but ether-vapor had been inhaled in the chemistry-class at the college as well as nitrous oxid in the same manner from a bag, while Hutchinson's spirometer was then in daily use. A more efficient means of administration was evidently needed, and Liston drove me to my uncle's laboratory to see what better means could be devised.

My confidence in success was unshaken; I had breathed ether in the College demonstrations, and had noticed that while under its influence my knuckles were bruised against the iron edge of the class-room desks without any sense of pain at the time. With a larger supply of vapor than that supplied for inhalation at the College, less excitement and further insensibility might be produced. Among the glass vessels in Oxford street was one sufficiently large, with an opening below where a good-sized tube could be fixed, and a larger one above where more ether could be introduced; this was at first closed with a sponge, a suitable tube was fitted into the lower opening, and for a mouthpiece a folded towel was bent into a funnel, the tube inclosed in the apex of the cone,[1] and when Liston returned in the afternoon all was in readiness. Enough ether to produce the volume of vapor required to fill the vase was put into it, and the upper opening filled with a new sponge on which the same quantity of ether was poured, and I commenced inhalation. At first I could not hold the cone close to my face, but soon took it in deep

[1] Sir B. W. Richardson, "Biological Experimentation," London, 1896, p. 47.

[1] The sponge soon found its way into the cone, or the ether was sprinkled there without the intervention of jar and tube.

breaths, and evidently soon became unconscious and dropped the tube. Liston made a small puncture under my finger-nail, and was satisfied as to my insensibility to pain. It was arranged for us to meet at Mr. (now Sir Edwin) Sanders' the next morning, and, as my uncle had to be in his hands, he would try its effects.

I made further experiments upon myself on Saturday, and my uncle's chief assistant, Mr. John Taylor, now of 14 Baker street, consented to a further experience. At this time a small glass vessel with two openings, one fitting into the larger vase and another at top, was used to contain the sponge, and a larger supply of ether was used. When my subject began to tolerate the stronger vapor, I brought the smooth base of the cone over the nose and the lower end of it under the chin, and a very quiet and complete anesthesia was produced, which lasted some minutes after the inhalation ceased. The meeting at Mr. Sanders was deferred, and Liston, after further demonstration in Oxford street, arranged for the removal of the diseased knee next day at the hospital, the patient being only too glad to submit himself to the prospect offered him. Notes were sent to several men of eminence in the profession, among others to Mr. Wakley, who was present; Mr. Cadge, now of Norwich, accompanied Liston; Dr. Ransom, now of Nottingham, was one of Liston's dressers at this time. On Monday I took the glass vase and a supply of ether prepared by my uncle to the hospital. I have seen it stated by an intimate friend that he was present at the operation, but neither he nor my friend were in the operating-theater, and neither of them had much liking for that arena. A similar mistake as to my uncle's administering ether for surgical operations has been made more than once.

The first operation in London under ether has been described elsewhere. A more striking display could hardly be imagined; the general effect upon the foremost professional men present was almost of awe, yet not unlike that expressed by the American surgeon Warren, after his first operation under ether, administered by Dr. W. T. G. Morton, "Gentlemen, this is no humbug." Liston said nothing. My own sensations were chiefly directed to the aspect of the patient; the look of alarm on his emaciated pale face soon gave way to the flush of ether; his quiet breathing and calm repose were a joy to witness. When unconsciousness was reached, Liston completed the amputation at the thigh by the flap-operation in twenty-eight seconds from the first thrust of the knife to the last touch of the saw. It had been arranged for the arteries to be tied after the patient had been carried from the operating-table to an adjoining room, but his deep and quiet sleep continuing, the arteries were leisurely secured, and the flaps closed in Liston's usual manner, and neatly dressed, before the return of consciousness was announced by the patient's old cry of, "I can't have it done, I must die as I am." On being told that all was over, he said he still had pain extending to the toes, then when gently raised to see the shortened limb the look of delight in his face will never pass from my mind while memory holds its place. Liston could hardly speak at first, and finally said that he was as surprised as those around him.

Had I not myself felt that ether could annul pain and seen it inhaled in the chemistry-class; had I not been so much noticed by Liston and interested in this particular patient; had I not had the resources of my uncle, Mr. Peter Squire, at hand, and been assisted by his experience and ready invention, the full effects of this anesthetic would not have been obtained and made so evident in the course of one or two critical days. The next few days were fully occupied in administering ether-vapor and inhaling it myself. Some failures were met with small tubes, where imperfect mouthpieces or insufficient vapor were used. One Friday evening, soon after Christmas, I went with Mr. Taylor to the Royal Institution with a somewhat cumbrous inhaler, where he submitted to complete anesthesia at my hands before the assembled members.

During a short Christmas holiday my respiration was so impeded by frequent inhalations of ether that I could not face the outside coach-journey of forty miles to my home in Bedfordshire. I returned to my interrupted medical studies henceforth in close company with Russell Reynolds. I once gave ether for Dr. Murphy in some obstetric difficulty; sometimes I gave ether at the hospital until Thomas Park and Clover took it up, and there met Dr. Snow. Chloric ether, used by Morton before sulphuric ether, was tried, I believe, at St. Bartholomew's Hospital, the form used, like the American preparation, containing more chloroform than that in our Pharmacopœia. Chloroform had been prepared by Soubeiran ten or twelve years earlier. Liston was informed by Mr. Syme of Simpson's use of chloroform, and again asked me to administer it. Subsequently my chief reliance was on this anesthetic. For the mixtures of chloroform with ether and spirit, whether under the designation of methylen, A.E.C., or other names, in cases of labor, Junker's method of administration seemed specially suitable.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION.

Thirteenth Annual Meeting, held at the Mott Memorial Hall, New York, October 13, 14, and 15, 1896.

FIRST DAY—OCTOBER 13TH.

NELSON L. NORTH, M.D., of Kings county read a paper on

FUNCTIONLESS ORGANS—ARE THERE ANY? A POSSIBLE USE OF THE APPENDIX VERMIFORMIS,

in which he referred to the numerous organs which, not very long ago, had been considered rudimentary, or functionless, but which were now known to have their office to perform in the human economy. It had seemed to him that the much-abused vermiform appendix had been created for some other purpose than to be ruthlessly sacrificed to the surgeon's knife, and in the numerous follicles of the appendix he found what seemed to him positive evidence of glandular action. His idea was that its office was to close the ileocecal valve and prevent the regurgitation of foul gases into the small intestine. The author then quoted at length statistics from the Brooklyn Board

of Health, to show that, in spite of the advancements in surgery, the death-rate from appendicitis and allied disorders had been steadily on the increase. He explained this by supposing that proper medical treatment was not given at the beginning of these affections—that many of the present generation of medical men had already forgotten the important lessons taught by Alonzo Clark and others. His own long experience in practise had long ago convinced him that the early and intelligent use of mild purgatives and enemata, together with the bold use of opium, when peritonitis threatened, would serve to cure many cases of appendicitis which physicians at the present time were prone to abandon at once to the surgeon.

DR. JOHN CRONYN of Erie county said that the medical treatment would be found all-sufficient in a large proportion of cases of appendicitis, if the physician would begin the treatment by giving a large dose of calomel, and follow this up by a liberal use of opium and the application of an ice-bag or a poultice to the affected region.

DR. WILLIAM M. BEMUS of Chautauqua county said that he had had good success in the treatment of this condition by the use of opium internally and an ice-bag externally, assisted by cold-water enemata. He asked Dr. Cronyn when he would apply ice and when poultices.

DR. CRONYN replied that if the case were seen early, the ice-bag should be used; if in a later stage, the poultice would probably be more appropriate.

DARWIN COLVIN, M.D., of Wayne county, the President, devoted his address to

MEDICAL EXPERT TESTIMONY.

Nothing, he said, was more degrading than to hear the medical expert constantly speaking of "our side." When the medical expert was appointed by a power entirely remote from either party to the suit, and was properly remunerated by a daily allowance, then, and not until then, could one look for much improvement in such testimony.

J. W. S. GOULEY, M.D., of New York county read an elaborate paper on

PROSTATIC ENLARGEMENT.

Diffuse increase of the muscle-tissue constitutes the greater part of the substance of some hard prostates. The most common form is chronic progressive enlargement of the prostate, a condition found in about forty per cent. of men between fifty and seventy years. Out of this number, however, only about one in six suffers from any serious interference with urination.

In the treatment of these cases, irrigation of the bladder is an important part. For this purpose, he favors the use of a 1–1000 solution of formalin, or of a 1–10,000 solution of corrosive sublimate containing one per cent. of phenol. Very weak solutions of nitrate of silver also act beneficially on the vesical epithelium. If very foul, the bladder should be washed out with the sublimate solution in the morning, and in the evening with the silver solution. The use of metallic catheters, either by patient or physician, was to be condemned, and it should not be forgotten that unclean or rough catheters were often the cause of much mischief. The indications for operative interference were: When the bladder was permanently contractured and its capacity inordinately reduced; when catheterism was extremely difficult or was followed by rigors, and in some cases in which auto-catheterism was not practicable. Early operative interference was justifiable, because it tended to prevent the occurrence of lesions which result from the retention and stagnation of the urine. It was, however, contraindicated when the upper urinary organs were much diseased. Where there was malignant or tubercular disease of the prostate, or slight disease of the upper urinary organs, palliative operations were called for. These were: Suprapubic cystotomy, the establishment of a suprapubic fistula, dilatation of a false route, and capillary puncture of the bladder. The first method was of much value in malignant or tubercular disease of the prostate. Dilatation of a false route was to be accomplished by the use of a special instrument, called an "invaginated catheter." After this operation, spontaneous micturition would ordinarily be possible for two years, and after this time, although catheterism would be required, it would be comparatively easy. Capillary puncture was rarely necessary, although in some emergency-cases it was proper to resort to it *once* to relieve intense suffering. Statistics showed that repeated capillary puncture was unwise. Among the radical operations performed were: Excision of urethro-vesical bars, excision of the central portion of the lower third of the isthmus, excision of vesical growths, and more or less complete removal of the prostate itself. Experiments on the cadaver had shown that the soft variety of prostatic enlargement could be readily enucleated, and this was the form most commonly met with in elderly men. Among the greatest and best operations ever devised for performance on the genito-urinary organs, he would class Dr. S. Alexander's method of doing prostatectomy. The operation could be done rapidly and thoroughly, with but little hemorrhage and injury to urethra and bladder, and it provided for efficient drainage, through both the suprapubic and perineal wounds.

DR. SAMUEL ALEXANDER of New York county said that in the management of enlarged prostate the choice lay between the use of a catheter for the rest of the patient's life, the removal of the prostate, or the formation of a permanent artificial channel for the urine. The value of catheterism depended largely upon the care with which it was done, and hence it was more applicable to intelligent people of leisure than to the ignorant and busy laboring man. In some cases, however, the most careful catheterism failed to give relief. Radical operative interference was indicated in the following conditions: (1) When the degree of retention was such that the patient was almost constantly dependent on the catheter; (2) when there was marked and persistent vesical irritability, due to intravesical growths; (3) when the amount of residual urine is on the increase; (4) when catheterism was becoming more difficult, and frequently followed by hemorrhage; (5) when even careful catheterism produced cystitis; (6) in long-standing cases of vesical inflammation, that have not yielded to other treatment; and (7) when the patients could not or would not use the catheter aseptically. He had performed his operation of prostatectomy first in January, 1894, and had done it altogether

eight times, with but two failures. In all but one of the six successful cases the ability to empty the bladder completely had been restored. Even the completely atonied bladder would, in most instances, regain its tone, even after years of obstruction, and usually, after this operation, voluntary micturition would be restored.

Dr. W. G. Brownson of Noroton, Conn., described his experience in treating old soldiers suffering from enlargement of the prostate. He said that at his institution he had succeeded in giving comfort and happiness to many an old soldier by a simple method of palliative treatment. In cases in which a soft catheter could be introduced, these old men could be kept in fair condition by daily washings of the bladder. For this purpose he preferred a mixture of carbolic acid, glycerin, and water, 1 to 200 or 500. From two to four ounces of the solution were allowed to run into the bladder from a fountain-syringe, and each washing was kept up until the solution came away clear. It was rarely that more than one washing a day was required.

Dr. Douglas Ayres of Montgomery county said that in most instances complete retention of the urine was one of the latest symptoms. In the early stages, much good could be done by advising the patient regarding the proper clothing of the body, the necessity for evacuating the bladder at regular intervals, and by insisting on moderation in exercise, food, and drink. The regulation of the bowels was by no means an insignificant part of the management of these cases. The quantity of residual urine should be determined early, and if the urine were found to be sterile, and to amount to more than about two ounces, the catheter should be used, the frequency of its introduction being governed by the quantity of residual urine. At first, sterilized water, at 100° F., would be found useful for irrigation.

Dr. E. D. Ferguson of Rensselaer county said that in cases demanding drainage of the bladder he had found it useful and convenient to insert the tube to the desired depth, and then secure it in this position by one or two stitches passed through the skin and subcutaneous tissue.

Dr. H. O. Marcy of Boston predicted a brilliant future for Dr. Alexander's operation of prostatectomy, but thought the perineal opening would secure sufficient drainage, without the suprapubic wound.

Frederick Holme Wiggin, M.D., of New York county presented a paper on

THE TREATMENT OF FECAL FISTULÆ, WITH REPORTS OF CASES.

He described in detail three cases of fecal fistula, two of which had been previously operated upon unsuccessfully in another city. These failures were, in all probability, due to the neglect to break up thoroughly the adhesions which, by preventing a free passage of feces, had caused a reopening of the fistulæ. There is but little danger of septic peritonitis arising from accidental discharge of the contents of the bowel into the peritoneal cavity, if the parts are washed with a fifty-per-cent. solution of hydrozone, and followed with saline solution. Used in this way, the hydrozone would not irritate the peritoneum, and, in his experience with this method since 1893, he had found it quite possible to meet successfully this formerly grave complication.

Dr. Marcy heartily concurred in the views expressed in this paper. He said that a number of times, in operating on these cases, he had thought it wiser to leave the original cavity entirely alone, making the incision in the median line, and then dissecting off the adhesion of the intestine to the abdominal wound. The peritoneal opening of the fistula having been closed off, there was only left an external wound, which could be readily treated by dissection. The opening in the bowel he preferred to close by a double-tendon suture, reflecting over it the peritoneum.

Joseph D. Bryant, M.D., of New York county read a paper on

IRRITABLE STUMP.

He reviewed the statistics of the late war, and gave the results of some inquiries that he had made among the makers of artificial limbs. From them he had learned that the important points to secure a useful stump were: (1) A sufficient length of flap to prevent traction on the stump; (2) a movable cicatrix, and (3) a periosteal covering for the divided ends of the bone. The author then described the method which he had found satisfactory in dealing with irritable stump in the lower third of the leg. The important points were: (1) A circular flap is made in the lower third of the leg, of a length a little greater than one-fourth of the circumference of the limb at the point of division of the bone; (2) after reflection of the flap upward equally for half an inch, a transverse incision is made across the subcutaneous surface of the tibia, at the line of reflection of the flap, and through the periosteum; (3) division of the periosteum at the limits of the anterior and posterior borders of the subcutaneous surfaces of the incisions, by an incision in the long axis of the tibia, the periosteum being pushed up, instead of dissected, along with the anterior flap; (4) a portion of the flap corresponding to the subcutaneous part of the tibia is lined, therefore, with the detached periosteum, which falls over the end of the bone when the flaps are adjusted; (5) the tibia is divided transversely on a line with the periosteal reflection, and the fibula, one-fourth of an inch higher up; (6) the flaps are coaptated obliquely on a line with the subcutaneous surface of the tibia, so that the periosteal flap rests evenly over the end of the divided tibia. It was important, the speaker said, that the periosteal covering should remain connected with the superimposed tissues.

J. Lewis Smith, M.D., of New York county read a paper on

THE HINDRANCES TO THE SUCCESSFUL TREATMENT OF THE DISEASES OF INFANCY AND CHILDHOOD.

He dwelt upon the former erroneous notion that dentition was a source of many of the diseases of childhood, and also upon the popular fallacy that "growing pains" were a part of the natural process of growth. He said that this popular fallacy was responsible for the development of many cases of rheumatic endocarditis.

Reginald H. Sayre, M.D., of New York county presented a communication on

THE PRACTICAL USES OF RÖNTGEN'S DISCOVERY AS APPLIED TO SURGERY.

He had been able to take photographs of fractured limbs while still encased in plaster of Paris, thus enabling him to know beyond a doubt the position of the fractured parts. The method also was most admirable in recording the condition of cases of congenital dislocation of the hip, before and after operation, and also to distinguishing between true and false ankylosis. In the former the X-ray photograph would not show the usual gap between the ends of the bones. Owing to the translucency of the cartilaginous portions of the foot in the young child, skiagraphs of club-feet in these little ones were not very instructive.

Edward B. Dench, M.D., of New York county read a paper entitled

TREATMENT OF OTORRHEA AND ITS IMPORTANCE.

He said that a profuse, chronic, purulent aural discharge, which had lasted for over two months, could be assumed to come from the middle ear, and that a scanty purulent discharge probably came from the external meatus. While pressure in front of the tragus, or traction on the auricle, would cause adults pain in cases in which the external auditory canal was affected, this sign could not be relied upon in children, because in the latter there was no bony canal. A recent purulent otorrhea might be due to infection of the tissues about the meatus, or to infection of the tissues in the upper part of the tympanic cavity. Where proper drainage was provided the discharge would cease as soon as all the necrotic tissue had been discharged. The first object of treatment should be to secure free drainage, and the second, to keep the parts aseptic. When syringing out the ear in an adult, the auricle should be drawn outward, upward, and backward; in the case of a child, it should be drawn outward, downward, and backward. Peroxid of hydrogen was objectionable as an application to the ear, because it was irritating, and because the large volume of gas liberated when the solution came in contact with pus was liable to produce an injurious degree of pressure within the ear. The speaker said that he preferred to use a warm bichlorid-of-mercury solution, 1 to 3000 or 5000. Powders were objectionable, because they formed hard crusts and blocked up the canal, and plugs of cotton in the ear were liable to give rise to the formation of furuncles about the meatus. The importance of the subject treated in this paper was shown by the fact that one observer had reported that out of 820 cases of suppurative disease of the middle ear 2.5 per cent. had proved fatal.

Frank S. Milbury, M.D., of Kings county read a paper on

THE RELATION OF AFFECTIONS OF THE UPPER AIR-PASSAGES TO THE DISEASES OF THE EAR.

He spoke of the frequency with which middle-ear disease and deafness were dependent upon stenosis of the nasal passages. For this reason intranasal surgery often improved the hearing. Atrophic rhinitis and nasopharyngeal catarrh, and enlarged tonsils, were the cause of much disease of the ear, and adenoids, by plugging up the Eustachian orifices, gave rise to chronic congestion of the membrani tympani.

SECOND DAY—OCTOBER 14TH.

Thomas J. Hillis, M.D., of New York county read a paper on

THE TECHNIQUE OF INTUBATION IN CHILDREN; SOME REMARKS ON THE TIME FOR OPERATION AND AFTER-TREATMENT.

In performing intubation it should be remembered that the larynx of the adult is much more deeply situated than in the child. It was better to wrap up the child, with its arms crossed over the abdomen, in strong muslin, as in this way more room was left for the operator's manipulations. Sometimes, instead of keeping the tube and introducer exactly in the median line, space was economized by first tilting the instrument so that the tube lies across the tongue. As soon as it touched the guiding finger, the instrument should be restored to the median line. As the cartilaginous rings of the trachea in infants under a year old are soft, it might be possible to remove the tube by "expressing" it with the thumb and finger, instead of removing it in the usual way with the extractor. If it is to be expressed, the child should be placed on the back, with the head thrown well back over a small pillow. Dr. Hillis spoke in the highest terms of the new and ingenious contrivance devised by Dr. Dillon Brown, to facilitate the removal of the tube from the larynx. There could be no exact rule laid down as to the length of time the tube should be allowed to remain in the larynx, but it were better to err on the side of leaving it in too long. After its removal there would always be more or less obstruction, so that if this were not very marked, it should not cause the physician uneasiness. Many have advised that while feeding a child wearing one of these tubes the little patient should be placed on its back, with its head hanging over the edge of the nurse's lap. He preferred to place the child on its stomach, face down, as in this position it had more command over the constrictors. No food should be allowed for at least one hour after the performance of intubation. The best food was bread soaked in milk or beef-juice, and oatmeal-porridge.

John Shrady, M.D., of New York county read a paper on

TEMPERATURE AS AN ELEMENT IN PROGNOSIS.

The problems of waste and supply were to be considered in the light of sex, age, temperament, and environment. High temperatures were not as uniformly fatal as low temperatures, and a high temperature of short duration usually indicated an acute infection. As a rule a subnormal temperature presaged death.

T. D. Crothers, M.D., of Hartford read a paper on

THE MEDICAL TREATMENT OF INEBRIETY.

He said that it was most important to study at the outset the etiological factors present in the individual case. The removal of spirits at the beginning was always followed by the best results, and the reaction could be neutralized by giving one-twentieth of a grain of nitrate of strychnia every four hours, and, if necessary, the bromids for

insomnia. The withdrawal of spirits should always be followed by a brisk calomel purge, the use of hot broths, and hot baths with vigorous massage. Where the patient insisted upon a gradual withdrawal, the strychnia should be given every two hours, and the wines and beers substituted for the stronger spirits. Many cases developed tuberculosis, or other serious organic disease, as a result of the removal of alcohol. In those who show premonitory symptoms of a relapse, a brisk purge, with baths and prolonged rest, will often avert the storm. Drugs, like apomorphia, which are intended to produce a disgust for liquor, are not reliable, and are usually dangerous. The strychnin was best given in combination with cinchona, or other vegetable tonic. Belladonna, hyoscyamus, and drugs of this class, are of limited value, and should be used very cautiously after the withdrawal of spirits. Very large doses of bromids are necessary—from 50 to 100 grains, but not for more than a few days. The speaker said that no single remedy was capable of meeting a wider range of indications than the Turkish bath, combined with massage. In conclusion, the writer stated his belief that if inebriety were more generally and more carefully studied, the results of treatment would be very much better.

H. O. Marcy, M.D., of Boston read a paper on

THE SURGICAL RELIEF OF OBSTRUCTION OF THE COMMON DUCT BY BILIARY CALCULI.

He said that he was the first person to operate for the removal of a calculus situated in the common duct, and that this operation had been performed in October, 1889. The walls of the common duct were divided with scissors and their edges everted from over the roughened calculus. The abdominal cavity had been shut off by sponges before this. With a fully curved needle, threaded with selected tendon-suture, the divided edges of the thickened mucous membrane of the duct and gall-bladder were united by a continuous suture, and over this was another layer of continuous suture, which united the edges of the peritoneum. A third layer of tendon-suture was then applied, the stitches being taken parallel to the long axis of the wound, through the peritoneum. Tension on this suture not alone buried it, but also the uninjured peritoneum, with exact coaptation. The peritoneum was then closed with a continuous double tendon-suture. The divided muscular layers were sutured in a similar manner, in separate layers, and the skin was united by buried tendon-sutures. The patient made a very satisfactory convalescence. When dried, the calculus weighed fifty-nine grains.

Sidney Yankauer, M.D., of New York county exhibited a simple and very inexpensive microtome which he had devised, and which had been found capable of doing as good work as microtomes costing as high as $50.

Dr. Yankauer also exhibited a new plaster-cutter, consisting of three circular plates, having knife-like teeth, and all rotating together like a circular saw. Owing to the peculiar construction of the teeth they did not become clogged with the plaster of Paris.

H. A. Haubold, M.D., of New York county in a paper on

THE PHYSIOLOGICAL DEDUCTIONS REGARDING THE USEFULNESS OF SO-CALLED ANIMAL EXTRACTS,

expressed his disbelief in the efficacy of animal extracts, including the nucleins and protonuclein, and based this opinion on certain physiological considerations. It had been claimed that when the nucleins were administered hypodermically, they gave rise to leucocytosis, but this, to his mind, was only an indication that the blood was making a special effort to rid itself of the foreign substance.

William H. Robb, M.D., of Montgomery county read a paper on

ONE POINT IN THE TREATMENT OF ENDOMETRITIS.

He advocated the use of solutions of nitrate of silver, taking care previously to remove unhealthy secretions. For mild cases, and for those seen early, he preferred to use a solution of the strength of five or ten grains to the ounce, reserving the strong solutions for the chronic and severe cases of endometritis.

Dr. L. J. Brooks of Chenango county said that undoubtedly there was an apparent benefit, at least for a time, after this mode of treatment, but careful observation would show that these applications, particularly the stronger ones, produced an atrophic and non-secreting membrane, which would cause much annoyance in the future.

Dr. J. Francis Calef of Middletown, Conn., said that he found that very weak solutions of nitrate of silver (1 to 3000) were very soothing to inflamed mucous membrane; but in using these very dilute solutions, care should be taken that the water used for washing the surface contained no chlorids.

Dr. W. M. Bemus said that he had found peroxid of hydrogen and also galvanism useful in preparing the endometrium for the application of medicaments.

Dr. John Cronyn said that he had seen benefit frequently ensue from even strong applications of nitrate of silver. Curettage, in his opinion, was a fearfully abused operation.

E. D. Ferguson, M.D., of Rensselaer county read a paper on

A CLASS OF FATAL CASES PRESUMABLY DUE TO INTESTINAL PTOMAINS.

He described the clinical histories of eight cases of obscure, but virulent, toxemia which had come under his observation. Four of them were medical, and four surgical. In each instance the onset had been sudden, and the chief symptom had been the vomiting, first of mucus, and afterward of coffee-ground material. This was sometimes associated with slight icterus, and in every instance death rapidly supervened. The autopsies on two or three of the cases failed to throw much light on the condition, but served to exclude peritonitis, intestinal obstruction and sepsis. The cases had not been associated either in time or locality. The only explanation that he could offer was that some micro-organisms in the intestinal canal had, for some unknown reason, suddenly become active, and as a result of this activity there had rapidly accumulated in the system a powerful and lethal

toxin. This had also resulted in parenchymatous hepatitis and softening and acute atrophy, for these changes were observed at the autopsies. It was evident that in at least some of the cases there was no intestinal obstruction—*e. g.*, the last one, for the bowels moved freely up to the day of death. He would venture the opinion that the cause might be either a bacterial ferment or enzyme, or else that as a result of unusual nerve-inhibition the digestive processes were profoundly disturbed, and so gave rise to the production of this virulent toxemia.

J. E. JANVRIN, M.D., of New York county described

TWO INTERESTING CASES OF SURGERY OF THE KIDNEY.

The first was a case of multiple abscess of the left kidney, complicated by Bright's disease, in which nephrectomy was performed and death occurred from uremia six days after the operation. The second was one of fibrolipoma of the capsule of the kidney, which was successfully removed by laparotomy.

NATHAN C. BOZEMAN, M.D., of New York county, presented a paper on

THE PALLIATIVE TREATMENT OF CANCER OF THE CERVIX AND BLADDER IN WOMEN.

He emphasized the importance of early recognizing and relieving the partially strictured condition of the vagina by the use of intra-vaginal dilators, worn for several hours each day. He had found it very useful in these cases to employ continuous irrigation of the bladder, for a vesico-vaginal fistula due to carcinomatous ulceration should never be closed.

R. ABERDEIN, M.D., of Onondago county spoke on

THE BROMIDS AS A CURE IN DIPHTHERIA.

He said that his friend, Dr. Knight, had observed the beneficial action of the bromids on diphtheria incidentally during an epidemic of that disease in the insane asylum. Following out this suggestion, the speaker said that he had tried the method in thirty-five cases, some of them quite severe, and had lost only two of the patients—one a child of five, and the other a child of eight years. In no case had the remedy produced bromism or irritability of the stomach.

W. T. LUSK, M.D., of New York county spoke on

RECENT INVESTIGATIONS CONCERNING ECLAMPSIA.

He called attention to the fact that many cases of slight albuminuria during pregnancy did not terminate in eclampsia, and that, on the other hand, eclampsia not infrequently occurred without any evidence of albuminuria or other abnormality of the urine. A diminished quantity of urea would indicate an excess of other poisons resulting from tissue-changes. At the present time, a plan of treatment that found much favor abroad was to place the patients showing slight albuminuria, with perhaps slight nervous symptoms, on a diet of at least two quarts of milk a day, and carefully regulating the bowels. Where there were headache and epigastric distress associated with albuminuria, he would be disposed to induce premature labor, but he would not care to interfere if there were no symptoms excepting the albuminuria. Ordinarily, he would prefer the use of Barnes' dilators, but in exceptionally urgent cases it might be justifiable to make the four incisions into the vaginal portion of the cervix recommended by Dührssen. If this were done, the incisions should be sewed up immediately after delivery. Where the eclamptic patient showed turgid blood-vessels, the removal of sixteen ounces of blood from the arm would act more efficiently than any other known measure.

WILLIAM M. BEMUS, M.D., of Chautauqua county read a paper on

THE DUTY OF THE PUBLIC TO THE PHYSICIAN,

which dealt chiefly with certain legal points not infrequently arising in medical practise.. He said that if a physician were sued for malpractise, and won the suit, it was quite likely that he would have to pay costs, owing to the plaintiff not being a responsible party. As a rule, anything warranted by good practise, and not objected to by the patient, is justified in law.

A. A. HUBBELL, M.D., of Erie county in a paper entitled

A PLEA FOR THE GENERAL USE OF MEASURES TO PREVENT OPHTHALMIA NEONATORUM,

showed by statistics that ten or fifteen per cent. of those who have had this disease are blind in both eyes. In the Credé method of prophylaxis, the child is put into a bath as soon as the umbilical cord has been tied, and then the lids are cleansed with absorbent cotton, and a single drop of a ten-grain solution of nitrate of silver is instilled into each eye. As the disease often occurs in cases in which there is not the slightest ground for suspecting that the mother has had gonorrhea, the need of carrying out some such preventive method in the case of every newborn child is manifest.

CHARLES PHELPS, M.D., of New York delivered the address on

SURGERY.

He said that, in the surgery of the past, the diagnosis was often made in the absence of positive data, with an accuracy that made the surgeon's judgment seem almost like intuition. The established dependence of suppuration on the presence of streptococci had revolutionized surgical practise, and this discovery had been followed by both a cure and an absolute means of prevention. It was probably the most conspicuous achievement of contemporaneous surgery. Dr. Phelps devoted the greater part of his address to a consideration of the ethical side, criticizing chiefly the strong tendency at present for surgeons to exploit themselves in the daily papers and elsewhere. The remedy, he said, was to be found in a better preparatory and medical education—a broader culture in all those things which go to make up a true gentleman, and one worthy of belonging to an honorable profession.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 13, 1896, TO OCTOBER 19, 1896.

PROMOTIONS.

Lieutenant-Colonel C. R. Greenleaf, Deputy Surgeon-General, to be Assistant Surgeon-General, with rank of Colonel, October 10, 1896, vice Town, retired.

Major William H. Gardner, Surgeon, to be Deputy Surgeon-General, with rank of Lieutenant-Colonel, vice Greenleaf, promoted, to date October 10, 1896.

ORIGINAL ARTICLES.

NOTES ON THE MANAGEMENT OF INCURABLE CASES OF CANCER.[1]

BY DANIEL LEWIS, M.D.,
OF NEW YORK;
SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL.

THERE is no longer any ground for discussing the question of the curability of cancer. The statistics of numerous surgeons not only place on record many permanent cures, but also conclusively show that improved methods of treatment and perfected surgical procedures are slowly, but steadily increasing the percentage of patients who have remained well beyond the three-year period, which has been adopted as the time-limit beyond which recurrence of the disease rarely happens. In the history of nearly all cases, there is doubtless a period which Mr. Jonathan Hutchinson has characterized as the precancerous stage of cancer, when acuteness of diagnosis and immediate removal of the suspected neoplasm would effect a cure. This stage, however, is usually passed before the patient applies for treatment at our surgical clinics, as the records of all hospitals clearly demonstrate. This leads me to say that the family physician is often charged, perhaps unjustly, with advising delay in the early history of these cases, and thus allaying present anxiety at the expense of the prospects of future successful treatment. If I were asked to formulate in a single sentence the most important factor in the effort to reduce mortality from cancer, I should reply: A thorough study and appreciation of the predisposing and exciting causes of the disease, by the family physician.

When the diagnosis shall be made in the very early stage and treatment shall be at once prompt and radical, the number of incurable cases, of which we are to speak, will rapidly decrease, and the proportional decrease of mortality will mark a new era in the surgery of malignant diseases.

At present we are called upon to attend many patients where every method of treatment has been a failure and nothing remains but such palliative measures as are at our command for smoothing the downward road to the inevitably fatal termination.

[1] Read before the Medical Society of the County of New York.

The resources which may be employed to advantage in these hopeless cases vary according to the site of the disease and, in some degree, to the temperament of the patient.

The remedies indicated may be classified, for our present purpose, as follows: (1) Psychological influences; (2) medicinal agents; (3) surgical operation; (4) local applications, dressings, antiseptics, etc.; (5) anodynes; (6) inoculation with various toxins.

The influence of the mind upon the course of disease is very marked in many other conditions, and we have reason to believe, with Dr. Herbert L. Snow of the London Cancer Hospital, that mental anxiety is sometimes even an etiological factor in cancer. You will all recall the fear which many a neurotic patient experiences because of the supposed hereditary character of cancer. This, the surgeon can confidently assure the sufferer, is no longer believed to be an important question—that the preponderance of clinical testimony is against the old theory that heredity has any influence whatever upon the origin and course of such diseases.

The exact knowledge of the nature of the disease should be withheld from the patient as far as possible, and the use of the term "cancer" studiously avoided. You may designate the case a "malignant growth," a "tumor," a "sarcoma," or anything else except the dreaded word "cancer," without destroying the patient's hope of relief or cure. So powerful is the depressing influence of this fear of cancer that it has been many years since I have used the term in the presence of a patient. When the question is asked, "Is this a cancer?" a truthful description can be given of the nature of the disease without the use of this dreaded designation. We are often led to prescribe tonics in such cases, but hope is the very best one, and will effectually insure a tranquil nervous system, with all which that condition implies, and, in my judgment, we should never unnecessarily deprive the patient of its influence.

Medicinal agents have been brought forward from time to time, sanctioned by authorities, which cannot be reasonably ignored. While many of these are chiefly useful in their influence upon the mental condition of the patient, some of them decidedly influence the course of the disease.

Inoperable cancer of the breast, for example, has, in some cases, been arrested in its growth and infiltration of adjacent tissues diminished by hypodermic injections of 20 drops of a ten-per-cent. solution of the chlorid of anilin in dilute alcohol, repeated every second or third day. This treatment may be continued for several weeks or months. The usual antiseptic precautions are to be observed in the preparation of the skin at the point of injection, and of the hypodermic syringe. My attention was first called to this remedy by Dr. C. E. Bruce, who had secured marked improvement therefrom in an inoperable epithelioma of the tongue. I have elsewhere reported a case of recurrent disease of the right breast, in which a large, painful tumor, which was firmly attached to the chest-wall, became almost painless, reduced in size, and quite movable upon the thoracic wall, and its removal by operation became possible, and was advised. The patient, however, elected to continue the treatment which had induced such changes in the growth, and she left the hospital, and the subsequent history is unknown. I have no doubt, however, that the influence of the anilin was not permanent and, after a large trial of the plan in cases of cancerous breast, we can say that as a palliative measure only it is useful, and that it should not be neglected where ulceration has not yet occurred.

In an extensive cancerous disease of the tongue, marked improvement resulted from these injections, and the patient's life was prolonged many months, with much relief of pain, until near the termination of the history. There is never any serious reaction following these injections, and no local irritation at the point of puncture.

Methylene blue, administered in pills (gr. ii–v), in combination with arsenic (gr. $\frac{1}{60}$), has been recommended for cancer of internal organs, and improvement sometimes follows its use, especially when the disease is in some portion of the alimentary tract. This remedy causes no gastric disturbance, and may be given every six hours for an indefinite period. I have thoroughly tested its efficacy in a single case, in which the disease proved to be in the pancreas. For a time there was a mitigation of symptoms. In cancer of the stomach, its action is probably more pronounced, owing to the local effect of the drug.

In a paper read before the Medical Society of the State of New York in 1890, I described the method of using Chian turpentine in cancer as recommended by Professor Clay of Birmingham, and expressed the opinion that it might prove useful in some cases of uterine cancer. Experiments with it have been continued, and it is with regret that I must declare that no such results as Clay published have ever been observed in my practice. Its employment has been abandoned in the New York Skin and Cancer Hospital, and also in the London Cancer Hospital, where Mr. Jennings accorded it a thorough trial.

Many other remedies have been recommended by various writers, and it is not unreasonable to hope that new ones will be brought forward which will be worthy of trial in these inoperable cases, and even a specific for cancer may finally be discovered, as Sir James Paget has predicted. The preliminary tests of all such remedies should be made only upon inoperable cases, as we should never for a moment trust a patient's fate to such means, to the exclusion of operative procedures, when it is possible to accomplish complete removal of the neoplasm.

Surgical operation, in hopeless cases, may be indicated in two conditions: (1) To save important organs, and (2) to relieve the patient of a mass of diseased tissue. In disease of the orbit, for example, the unaffected eye may be saved for years by persistently removing the infiltrated border of the ulcer which is nearest to the healthy side. One of my patients now has perfect vision in the right eye, which would have been lost years ago had we neglected this precautionary operation.

The partial removal of a cancerous uterus by the curette results in a lessening of hemorrhage and fetid discharges, which not only disturb the patient, but are a prolific source of annoyance to the attendants. The same course may properly be adopted with a cancerous tongue, or the external portion of rectal cancer, or any portion of the body in which the personal comfort of the patient may be thereby increased. I have even removed incurable tumors of the breast for the same reason, and secured a decided relief of distressing symptoms by the operation. These exceptional instances, however, do not invalidate the rule that operations for cancer should never be attempted unless we are reasonably certain that a thoroughly complete removal of the tumor may be effected.

Before leaving the question of surgical operation, a few words may be added concerning the management of irremovable cancer of the rectum. The most troublesome symptoms in these cases are due to obstruction, and when the passage of rectal bougies fails to afford relief, the somewhat formidable operation of colotomy is performed for that purpose. It often happens that the strictured portion can be reached by the finger, and if so,

it should be used for dilatation, instead of rubber instruments of any kind. The surgeon may so regulate the direction and extent of the force employed by the finger as to avoid perforation or other dangerous laceration. This procedure should not be entrusted to the nurse, but should be repeated by the surgeon every few days, according to the necessities of each individual patient. In this way I have avoided colotomy in nearly every case, and the patient has remained comparatively free from the symptoms dependent upon stricture.

There are several suggestions worthy of mention under the head of local applications, antiseptic lotions, and deodorants. Three years ago, Dr. Henry Bahnson of Salem, N. C., called my attention to antipyrin as a dressing for cancerous ulcers, and it is an admirable application. It is dusted upon the ulcer at each dressing, and the surface is then covered with absorbent gauze or cotton in the usual manner. Its employment prevents offensive odors, and decidedly improves the general appearance of the ulcer. The only objection to it is its expensiveness, and it has since been demonstrated that antifebrin and some other coal-tar products are equally satisfactory.

Protonuclein has recently been recommended as a possible cure for cancer. A careful test of its effects when employed externally has thus far proven its value as a stimulating antiseptic application. It is too early to determine the exact place this preparation deserves in the treatment of cancer, or whether it is in any sense a remedy, but as a local application the powder is a valuable addition to the list, and is to be classed with aristol and iodoform for that purpose. I may here state that the use of iodoform in private practice has become an inexcusable offence since these new remedies have been introduced, and there is no further necessity for a surgeon to render himself a nuisance to everybody he meets by dressing a case with iodoform-gauze or -powder.

If an ointment-dressing be indicated, aristol, with vaselin of suitable strength, is among the best (gr. xx to ʒ ii to ℥ i). This or any other ointment-dressing will be more grateful to the patient if spread upon a thick layer of absorbent cotton, instead of lint or gauze. The cotton is more easily adapted to every inequality of the ulcerated surface, and, from its lightness and tendency to cling to the surface when moistened, will seldom be displaced. The employment of fuchsin and other anilin preparations is not desirable, because of the staining of the patient's clothing and bedding, while the results obtained are no more satisfactory than with other dressings.

In cancer of the uterus, a deodorizing lotion is of the first importance, and one containing eucalyptus is preferable to a plain antiseptic solution. The vagina may also be loosely packed with cotton tampons, saturated with a solution (five-per-cent.) of aristol in albolene or benzoinol, a dressing which the nurse can readily renew. A vulvar pad of finely prepared oakum is both absorbent, a good deodorant, and cheaper than cotton, and is equally useful in advanced cases of cancer of the rectum.

No mention would be made of the use of opiates in incurable cases, were it not for the fact that the question is often asked regarding the extent to which they should be administered. The reply to that query should be: Give enough opium or morphin (or other anodyne) to insure the patient's comfort, if possible, without danger from the drug itself, the frequency of the dose to be determined by the patient. Such cases as we are considering have passed beyond the point where the danger of the morphin-habit should be considered. Suppositories, when the disease affects pelvic organs, morphin (or cocain) locally when desirable, hypodermic injections when more general narcosis is required, are all humane measures, and to withhold them is cruel, and almost criminal.

The deepest interest has been manifested by the profession and the laity in the employment of toxins, especially those of erysipelas, as remedies for cancer. The theory is the natural outgrowth of the germ-theory and of the presumption that there is a cancer-microbe which cannot coexist with the more active one found in erysipelas. The antagonism between these two diseases has often been noted, and twenty years ago, Dr. Morgan, who attended the cancer-wards of the Middlesex Hospital, London, was accustomed to make a more favorable prognosis if an operation had been followed by erysipelas during the healing-process. There are instances on record where a supposed epithelioma of the skin has been cured by this acute dermatitis.

The employment of the erysipelas-toxin, however, is a different matter. I now have records of many cases treated by these injections. Not a single case has been cured; one has been greatly improved (the disease being internal and the diagnosis doubtful); some have been slightly improved; there have been several deaths accredited to the toxin, and in many instances the results were negative. At a later period, I shall publish the histories of such cases as occurred in my own

practice, and only refer thus briefly to the subject now to emphasize the fact that thus far we have not passed beyond the stage of experiment with this agent, and all theories and prognostications of to-day may finally require amendment and perhaps be abandoned altogether.

It is intended that these notes shall be considered merely suggestions, which may be familiar to every one who has the care of many cancer cases. However, the surgeon's duty often leads in the direction of palliative treatment, and there is no class of cases which is so worthy of such unsparing attention to the minutest details as that now under consideration.

We should not too readily relegate a patient to the list of incurables, but be guided by the fact that while an operation in the very early stage is likely to produce a permanent cure, the more advanced cases, under present methods of operation, often yield results which are as gratifying as they are unexpected.

PHLYCTENULAR OPHTHALMIA.

By T. C. EVANS, M.D.,
of Louisville, Ky.;
Lecturer on Ophthalmology and Laryngology in the Kentucky School of Medicine; Member of the Louisville Clinical and Surgical Societies.

Phlyctenular ophthalmia is much more frequent in childhood than in adult life. It occurs commonly among the poor and underfed, especially those who live in overcrowded quarters with unsanitary surroundings, and in children who are the subjects of what we call "lymphatism." The percentage of cases occurring in the negro race is not greater than in the Caucasian, who have like surroundings. The frequency with which it complicates, or is complicated by, eczema, has led most of the recent investigators to regard it as an eczema of the conjunctiva and cornea. The phlyctenule itself consists primarily of a mass of lymphoid cells, beneath the epithelial layer of the conjunctiva or cornea. In the cornea this exudation or infiltration of cells usually takes place around a terminal filament of one of the corneal nerves. The central cells in the phlyctenule undergo necrotic changes, the epithelium over its surface is destroyed, and the papule or phlyctenule is succeeded by a small, crater-like ulcer. The hygienic surroundings, the general nutrition of the patient, the location of the ulcer, and the character of the microbic infection, etc., will determine whether the ulcer will speedily heal, remain stationary, or indolent, or become progressive and be complicated by an opacity or perforation. The relapses and recurrences of the disease, which are of common occurrence, are due to the formation of fresh phlyctenules. Each phlyctenule is from two to three millimeters in diameter, and each has its own area of congestion. The nearer they approach the cornea the more serious do they become, and the more unfavorable the prognosis in regard to duration, pain, and final termination. When the lesion is entirely within the conjunctiva, the process subsides rapidly after the ulcer is formed, and the healing is complete in from one to two weeks. When the lesion is in the cornea, the healing process is preceded by the development of blood-vessels from the limbus.

The subjective symptoms of the disease when it is confined to the conjunctiva are very slight, perhaps only an itching or burning sensation. When it affects the limbus or the cornea the pain is severe, both in the eye and in the supraorbital region; but the symptom most complained of is the photophobia, which is often intense, causing the child to bury its head in its mother's lap or in the bedclothing for hours and days together. The dangers from the disease are from perforation of the cornea, with prolapse of the iris; infection of the ulcer with hypopyon, iritis, or irido-cyclitis; corneal opacities; facets of the cornea with irregular astigmatism.

The ensemble of symptoms that accompany phlyctenular disease, the photophobia, the profuse lachrymation, the blepharospasm, the eczema, the nasal discharge and obstruction, together with the attitude of the patient, are so characteristic that the diagnosis is made even before the eye itself is examined.

In adults and tractable children a satisfactory examination can easily be made after the instillation of a few drops of a four-per-cent. solution of cocain; but in refractory children with blepharospasm it is better to resort at once to the use of chloroform rather than have a "scene," which always follows when an attempt is made to hold the child and force the lids open with retractors.

The treatment is local and general. The character and details of the local treatment will of course be determined by the stage, location, and complications of the lesion. The first indication is to keep the eye thoroughly cleansed by frequent washing with a solution of boric acid. If the patient is old enough the eye should be protected by smoked glasses. In the uncomplicated cases the old-time Pagenstecker's ointment of the yellow oxid of mercury still holds the first place in local therapeutics, though now no one in this country uses it in the strength advised by him in his article on the subject, *viz.*: from 30 to 60

grains to the ounce, though European and some of the American surgeons still advise from 10 to 24 grains to the ounce. Children tolerate the stronger ointments better than adults. I usually prescribe 1 grain to the dram, or 8 grains to the ounce, which rarely causes pain. In compounding the prescription it is important that the amorphous yellow oxid and not the crystals be used, and that it be rubbed down with a few drops of olive-oil before adding it to the base, unless the druggist is in the habit of compounding oculist's prescriptions. It is always well to specify this in ordering. The ointment should be applied inside the lids with a spatula or brush once or twice a day. Probably next in importance comes the instillation of eserin; this may be used from four to six times a day along with the ointment or other treatment. I rarely use the eserin-solution stronger than one-half grain to the ounce; more frequently one-fourth grain to the ounce. I think no one who has tried the effect of a two-grain solution in his own eye will likely prescribe it for his patients. While atropin is recommended in most of the text-books, it is contraindicated except in cases complicated by perforation or iritis. When the phlyctenules are confined entirely to the conjunctiva, the insufflation of calomel has been highly recommended. In the infected and indolent ulcer, more radical measures are indicated, the actual cautery or galvanocautery, or curettement, with the application of tincture of iodin or carbolic acid to its base. For the relief of the blepharospasm, dipping the child's head and face in a basin of cold water, and divulsion of the orbicular muscle with lid-retractors, are the means generally advised, neither of which can be carried out in private practice. The photophobia is partially relieved by the instillation of cocain, but the effect is transient, and I believe its constant and continued use retards the healing of the ulcers, and that it should not be used except for making an examination of the eye.

I have recently had considerable experience with subconjunctival injections of the bichlorid of mercury in phlyctenular ulcers of the cornea, with marked photophobia. It seems to limit the microbic invasion, and hasten the reparation-process, and very markedly lessens the photophobia. In several well-marked cases the patients have ceased to complain of the photophobia after the first injection. I inject from 5 to 15 minims of a 1–3000 solution. The eye is first thoroughly cocainized, and the injection is made with the ordinary hypodermic syringe. The injection of this amount of fluid into the cellular tissue will cause considerable ballooning of the conjunctiva, but the fluid is rapidly absorbed. The pain during and after the operation is as a rule inconsiderable. The injection is repeated in forty-eight hours. Whether the results are due to the therapeutic or antiseptic action of the mercury, or to the mechanical action of the fluid in flushing the lymphatics, has not been definitely determined.

The constitutional treatment is more prophylactic than curative in so far as the eye is concerned. When it is possible the improvement of the hygienic surroundings of the patient is of the first importance, but a large proportion, in fact the majority, of these unfortunates are surrounded by unsanitary conditions that are beyond the control of both the patient and the physician. The accompanying eczema should of course receive the appropriate treatment. The general nutrition should be looked after, cod-liver oil alone, or combined with the iodid of iron, is indicated in many of the cases. The discharge from the nose, which in children constitutes a troublesome and unsightly complication, is due not to disease of the nasal cavities but adenoid growths in the naso-pharynx. The removal of the growths must be accomplished by surgical means, preferably I think by the Goettstein's curette. It is impossible to remove or reduce them by any form of medication, either local or general, and to treat them expectantly is to subject the patient not only to the dangers of recurring attacks of phlyctenular inflammation, but to the whole catalogue of complications that follow on these hypertrophies. The faucial tonsils are also often hypertrophied in patients affected with phlyctenular disease. Their removal will add much to the patient's comfort, though the danger from these is not nearly so great as in the case of the pharyngeal tonsil.

THE USE OF PERMANGANATE OF ZINC IN THE TREATMENT OF GONORRHEA, WITH A REPORT OF FIFTY CASES.

BY A. S. HOTALING, M.D.,
OF BALTIMORE, MD.;
RESIDENT PHYSICIAN BAY VIEW HOSPITAL.

ONE who has had experience in the treatment of a large number of cases of gonorrhea knows how surely, as a rule, occasional failure follows one routine line, no matter how faithfully carried out. Absolute rules of practice cannot possibly be laid down in such a manner as to be applicable to every case and condition that may arise in the progress and extension of urethritis. The remedy which has given me the most satisfaction

in the largest number of cases is permanganate of zinc. It is a crystalline substance resembling permanganate of potash, and is very readily soluble in water. The drug in my hands has proven equally successful in the treatment of both acute and chronic cases. One remarkable characteristic of its action is the almost total absence of irritation following its use, the patient seldom complaining of pain.

Its effect is discernible almost immediately, the discharge in the majority of cases becoming greatly reduced after a few injections. The method of treatment is simple.

After the stage of acute inflammation has subsided, the injections are made four and five times a day after urination, with an ordinary blunt-pointed hard-rubber syringe, with a capacity of from three to four drams.

My rule is to begin with a solution of one-half grain to the ounce of water, gradually increasing it to one and a half grains. An alkaline diuretic is given, and the hygienic part of the treatment, which is of the utmost importance, is followed closely in every case.

The treatment was under my personal supervision, instead of being conducted by the patient.

I do not recommend permanganate of zinc as a cureall, but a perusal of the following summary of fifty cases will, I think, illustrate the value and utility of the drug. It might be advisable to state that the permanency of the cure was proven in nearly every case by the "two-glass test" and microscope.

In thirty-three cases it was the first attack of gonorrhea. The average duration of urethritis before the commencement of treatment was about three weeks. The average cessation of discharge after commencing the injections was nine days. Cure was pronounced permanent in an average of twenty days after treatment began.

In the above cases there were two failures; one where the injections were discontinued owing to the gonorrhea being complicated by orchitis. In the other the injections seemed to have no effect on the discharge, and the patient was eventually cured by another line of treatment. Of the remaining cases, ten had had previous attacks, and seven were chronic when they came under my observation in the hospital.

The average duration of the discharge in the cases with previous attacks, the cessation of discharge, and permanency of cure were practically the same as in the thirty-three cases first cited. Of these four failed to yield to permanganate of zinc, three being complicated by stricture. Cure was completed in these cases by the use of sounds after injections were discontinued, and one still remains in hospital, no success as yet having followed any line of treatment. The chronic cases had had gonorrhea on an average for six months, and in five cases success followed the use of permanganate of zinc even more rapidly than in the acute.

The two remaining were complicated by stricture and patches of granulation..

While the permanganate of zinc caused a cessation of the discharge, the urine, when voided, still contained shreds from the urethra.

This was cured under proper treatment.

[Since this article was first written, I have had eight additional cases, six acute and two chronic, all of which were cured by permanganate-of-zinc injections, making a permanent cure in fifty out of fifty-eight cases treated.]

IMPROVED METHOD OF EXPLORING THE THORACIC CAVITY.[1]

By J. McFADDEN GASTON, M.D.,
OF ATLANTA, GA.

Quenu, at the suggestion of Estlander, first executed section of the ribs without resecting them, while Delorme has improved upon this idea of a trap-door to reach the contents of the chest.

The process described by Delorme consists essentially in the formation of the flap from the soft parts of the thoracic wall and the ribs, which, when retracted, affords wide access to the field of operation. After the completion of the operation, the flap is replaced and sutured to the thoracic wall. The flap is formed as follows: An incision representing the three sides of a rectangle is made in the region between the third and sixth ribs. The base of the flap, then formed, is directed posteriorly and above, and its upper and lower margins run parallel with the ribs, and extend from the axillary border of the scapula to within three fingerbreadths of the sternum. At the anterior margin of this flap, the ribs and intercostal muscles are divided, while at the posterior margin only the ribs are divided to a limited extent. The flap is then loosened at its upper and lower margins and thrown back. This operation has been used by Delorme in a tuberculous abscess of the chest-wall, which perforated into the thoracic cavity, also in a fatal stab-wound of the chest.

Charles E. Jennings of London performs a similar operation for pneumonectomy, demon-

[1] Read before the American Surgical Association at Detroit, May 27, 1896.

strating it on the dead body. He makes an incision four inches in length, parallel to the lower border of the first rib, and carried outward toward the coracoid process. The skin, fascia, and pectoralis major are divided. A vertical incision must be made from the third costo-chondral junction below to the inner extremity of the horizontal incision above. The upper border of the pectoralis minor having been depressed, the second rib must be divided, first close to the outer extremity of the horizontal incision, and then through its chondral attachment. The intercostal muscles must be divided in the lines of the cutaneous incisions; a flap consisting of skin, fascia, pectoralis major, and part of the second rib and intercostal muscles can then be thrown down and the parietal layers of the pleura can be divided. This gives ample space for an operator's hand with the partial removal and replacement of one rib.

D. Lowson of Hull, England, made an incision from the midsternum along the course of the second rib, through the pectoral muscle, nearly to the edge of the axillary fold. From the inner end of this, he also cut for two inches downward along the middle of the sternum. The skin and muscle being reflected from the second and third ribs, the external intercostal muscles were separated above and below. The ribs were divided through the cartilage internally, and the bone externally.

The exposure of the cavity of the chest with the mediastinum may be most satisfactorily accomplished by the following procedure, for effecting a trap-door opening through the thoracic wall. The arm should be raised above the head. An incision is made in the mid-axillary line, directly downward, from the third to the eighth rib, inclusive or exclusive, without dividing the pleural lining. The first transverse incision is from the upper extremity of the perpendicular incision along the upper border of the third or fourth rib, the second from the lower extremity along the border of the seventh or eighth rib, as may be requisite, extending in front to the costal cartilage. Any bleeding should be controlled before dividing the parietal pleura in making either of these incisions. Scissors which have a blunt point on the internal blade may be used for dividing the pleura in each line, and if the lungs have not been collapsed previously, this will occur upon the entrance of the air into the chest. Upon elevating the detached margin of this flap, which includes all the structures of the thoracic wall, it will be found that the trap-door opens upon the hinges formed by the costal cartilage, and admits of thorough examination of all parts of the chest, including the mediastinum on the side of the operation.

The advantages claimed for this modification of the trap-door principle of exploration are the great simplicity in making the perpendicular axillary incision through tissues involving no complications, and the division of the ribs in a single line only.

It is evident that those who have adopted measures for gaining access to the thoracic cavity by a trap-door, have overlooked the advantages of using the costal cartilages for the hinges of the shutter.

So far as my investigation extends, this is the first occasion upon which this view has been presented to the medical profession.

NOTE.—The field of operation is so free from anything to complicate this exploration, whether for troubles of the lungs, heart, arteries, or mediastinum, that it should not require any special training for a surgeon to make this trap-door into the chest.

CLINICAL MEMORANDA.

LEPROSY.

BY W. T. ENGLISH, M.D.,
OF PITTSBURG, PA.

A MAN aged forty years, birthplace Pittsburg, Pa., height 5 ft. 9 in., weight about 130 pounds, of excellent family history, was admitted to the medical ward of the South Side Hospital, June 30, 1896, and examined by me in the presence of the internes.

His story was that he enjoyed good health in his early life, and when he became twenty years of age he embarked with an engineer-corps for South America. While engaged in the vicinity of Para, Brazil, his duties compelled him to be in the presence of miasmatic swamps, and at night he rested upon the ground. At the expiration of about ten months, he was stricken with a febrile ailment that prostrated him for several weeks. This malady was described as one of debility, weariness, chilliness, failure of appetite, and lassitude, akin to malarial poisoning. At about the same time the company with which he was engaged was stranded, and while awaiting means and tidings from his home he recovered his lost strength, so that he returned after the lapse of one year to his native place, apparently in robust health. This was in 1879. He married in 1881 in Indiana county, Pa. After three years of good health, spots or blotches appeared upon the skin in various parts of the body. Those upon the superciliary region speedily became red and ulcerated, destroying the hair of the brows. The surface of the face, neck, and ears became a deep red, and the ridges deepened until the whole countenance assumed a leonine fierceness. The hair distributed to the face is remarkable for its sparseness, but that upon the scalp is

well preserved. An accidental fall from a wagon is said to account for a depressed nasal septum. Upon the shoulders, arms, and forearms, the discoloration is at present of a brownish, coppery color, the eruption is irregular in form, and the skin is roughened. There is more or less desquamation and exfoliation of the cuticle upon the regions of the discolorations, but the surface is dry except when denuded. The patient relates that these spots began at and proceeded from the extremities, and that from circular blotches they became irregular by running together. It is thus established that the maculæ came first in a somewhat distinct form, and were afterward followed by more extended pigmentation. A certain

FIG. 1.

SHOWING DEFORMITIES OF FEATURES AND HANDS.

want of sensation or numbness is observed in the discolored portions, but upon the hands and forearms there is marked anesthesia. This is true also of the feet and legs to the knees. Nevertheless, he sometimes complains of neuralgic pains, and at frequent intervals he experiences deep-seated tingling, pricking, and burning pains in the palms and in the soles of his feet. The subcutaneous structures, including the muscles, are now becoming atrophied, especially the fingers and toes. The digits are thin, and are rolled in against the palm, while the nails assume a claw-like form. The toes of the left foot are forced down against the sole. There are depressions in the sites of the thenar eminences, due to defective nutrition of the muscles. The mucous membranes of the nose, throat, and mouth are congested and prone to ulcerate. The voice is husky. The conjunctiva is deep-red, and thickened and inflamed, and the eyes are overflowing with a tear-like secretion.

The patient traces the deformity on the foot to the appearance upon the sole of a hardened mass, which he attempted to remove, supposing it to be a corn, but cut too deeply and occasioned a suppurating sore, which was followed by contraction of the tendons. The warped condition of the hands he accounts for by experiences with burns and scalds against which he cannot guard, because of absence of sensation in these parts. Numerous cicatrices exist in the upper and lower extremities that are thus explained.

Further examination reveals the function of digestion fairly well maintained. The secretions are normal in quantity, chemically and microscopically. The mind is clear and active, and the spirits apparently cheerful. The circulation is good in the main, but the extremities are below normal temperature. The pulse is full, regular, and from seventy-five to ninety per minute, quickly changing with position and mental influence. The temperature observes the normal daily fluctuations and the usual altitude. Notwithstanding the anesthetic condition of the lower extremities, the patient maintains the erect posture and walks with reasonable certainty without the aid of sight. At present there are several denuded spots upon his hands which present unhealthy, purplish-hued surfaces, with a thin discharge glistening upon the surface, but occasion the patient no discomfort further than their un-

FIG. 2.

SHOWING MACULÆ ON UPPER EXTREMITIES AND BODY.

sightliness. Left knee-clonus is much exaggerated; the right is only slightly increased beyond the normal.

The diagnosis I have made is lepra anesthetica. Although there is some of the symptomatology of the tubercular form (lepra tuberculosa), it is very common to find these conditions intermingle. Dr. W. C. Foster, who has considerable knowledge of the disease, and also Dr. E. G. Matson, who visited several resorts of the lepers, confirm me in my opinion.

Microscopic examinations, made by Dr. T. L. Disque, of the secretions from the nose and eyes, further corroborate the assumption by discovering the bacilli of leprosy.

Besides the proof thus adduced, the manner of its acquisition appears very plain in the story as told by the patient. His sojourn in a leprous country, and the daily contact with the miasm that is the accredited cause of the malady, will satisfy those who believe it can only thus be brought about. To those who assume that it is contagious there is still evidence sufficient for their satisfaction in the fact that he was often in close relations with individuals suffering from leprosy. It will be noted that this is an incomplete picture of leprosy as it appears in the minds of those who know of it only by indirect knowledge. The stage of gangrenous sloughing has not yet fully developed. The slightest injury or abrasion may precipitate it. Already one finger has gone, as a result of a bruise, and the first phalanx of another digit is also wanting, from a cause too slight to occasion such a loss in one not affected with this malady. A singular persistence in like accounts prevails among all of those who are thus dismembered and deformed from leprotic disease. No matter how trivial or severe the defect, it is rare to find it attributed to its true cause by the subject.

The opportunity to observe this case included but a few days, as his friends speedily took him away from the observation and reach of those who discovered his malady.

To-day, leprosy is more promising of its harvest of death in America than at any previous point in its history. Hyde[1] gives a summary of cases of leprosy in the United States for 1894.

Statistics prove that our own countrymen have ceased to show the immunity from attacks of leprosy that they could once claim, and this case seems to be one in point.

A CASE OF HYDATID CYST IN THE PROSTATE GLAND, COMPLICATED WITH CYSTS IN THE PERITONEAL CAVITY AND LIVER.

BY WOLRAD WINTERBERG, M.D.,
OF SAN FRANCISCO.

THE patient was a carpenter, fifty-one years of age, married, and the father of six living, healthy children. He had never been sick until within two years, when he first began to be troubled with difficult micturition. Lately, his condition became so bad that he applied for medical assistance. His physician resorted to the use of the catheter, and when the patient got still worse he sent him to me for treatment in May, 1895. Patient, who was a tall, slim subject, looked pale and was extremely nervous. He told me that for over a year he had not had a good night's rest on account of his frequent desire to pass his urine. He only could void a very small quantity at a time, and sometimes none at all, so that the catheter had to be used.

He was losing strength and flesh and was unable to work at his trade. Inspection and palpation gave negative results, but digital exploration of the rectum revealed the presence of a large tumor about one inch above the anal orifice; it was sessile, immovable, and felt like a solid mass, which extended over the site of the prostate so high up that only by using considerable force could the examining finger reach the upper margin; laterally it extended about two inches from each side of the median line at its widest portion; it was perfectly smooth and regular in shape, and very tender on pressure.

By means of a No. 18 Nelaton catheter, the introduction of which caused a good deal of pain to the patient, about four ounces of urine were withdrawn. This was very turbid, of an ammoniacal odor, with an alkaline reaction, and contained much mucus and pus. My diagnosis was hypertrophy of the prostate. After two weeks of unsuccessful treatment by mechanical and medical means the patient insisted on being castrated, which operation I had previously held out to him as a last resort for the cure of his trouble.

On June 1st this operation was performed, after which, still during anesthesia, a silver catheter, No. 30, could be passed, and the bladder freely irrigated with a boric-acid solution; the urine was ordered to be drawn by means of a Nelaton catheter every three hours. The operation had been done about five o'clock in the afternoon, and about midnight I was called to the hospital, in which the patient had been placed, because the attendant was unable to catheterize the patient who suffered intensely from retention of urine. I found it necessary to chloroform the patient who had become so irritable that he was unable to control himself. I then evacuated the bladder by means of a soft catheter, which I afterward left *in situ*. In spite of this device I was again compelled to resort to chloroform on the following day because the permanent catheter failed to void the urine. From this time on I had to chloroform the patient about three times in twenty-four hours, and withdraw the urine by means of a silver catheter, since a soft catheter did not accomplish the desired results. This treatment was continued for a whole week, at the end of which I was again summoned to the hospital at midnight to see the patient. I found him in great agony caused by retention of urine and proceeded to withdraw it in the usual way, but utterly failed to get a drop of urine even with a metal catheter. I had the patient placed on the operating-table, and with the aid of a scalpel and catheter performed perineal section. On passing the finger through the perineal aperture I felt a large, tense, but somewhat compressible tumor, extending on a broad base from the prostatic portion of the urethra so far up into the cavity of the bladder, that the highest margin could not be reached by the tip of the finger; in front it was in close approximation to the anterior wall of the bladder; a very small quantity of urine followed the withdrawn finger, but when the catheter was introduced to a considerable depth a large quantity was immediately withdrawn. The bladder was then irrigated, a No. 18 soft catheter introduced, and replaced on the following day by a Nelaton No. 36. The patient from this time enjoyed relative comfort, but he had become highly emaciated, his appetite being very poor, the urine was very offensive, and the temperature ranged between 101 and 102°. The bladder was irrigated every three hours with potassium permanganate, and a tonic of iron, quinia, strychnia, and phosphoric acid administered.

On the 15th of June, while washing the bladder, I noticed that on lowering the funnel only a small fraction

[1] *American Journal of Medical Sciences*, No. 108, p. 251.

of the fluid injected into the bladder was returned; I refilled the funnel and the fluid disappeared rapidly on elevating the receptacle, but did not return. Presently the patient told me that he felt some fluid escaping from the rectum. I handed the funnel to an assistant with instructions to pour in some more fluid and elevate it, while I was watching the anal orifice. Very soon the permanganate-solution made its appearance through the anus and washed out the sac of a hydatid cyst. I then proceeded to a digital exploration of the rectum, and discovered an opening in the tumor so high up that it could just be reached by the tip of the finger. The result of a similar exploration of the bladder, through the perineal aperture, was negative; nevertheless, the presence of a vesico-rectal fistula had been clearly demonstrated, and, furthermore, this fistula had been caused by sloughing due to pressure from a hydatid cyst in the prostate gland.

Daughter-cysts were discharged at intervals, not only from the rectum but also from the bladder, which was irrigated hourly with a weak permanganate-solution, because a very offensive odor permeated the atmosphere of the sick-room; the rectum was washed twice a day with warm water. The temperature was still between 101 and 102°; pulse, 100, fairly strong and regular; anorexia; tongue heavily coated; extreme emaciation. After continuing the expectant treatment for about a week without any noticeable improvement, I decided to perform suprapubic cystotomy in order to get a clear inside-view of the bladder, digital exploration remaining negative, because the finger did not reach the fundus of the bladder, and the cystoscope was unavailable because there was no possibility of distending the bladder with the necessary amount of fluid owing to the presence of the vesico-rectal fistula. On the 22d of June the operation was performed, but besides a general hypertrophy and inflammatory condition, nothing abnormal was found in the walls of the bladder; in the upper portion of the prostatic urethra an opening was found through which the finger could be forced into the rectum; some empty cyst-sacs were found in the fistulous tract and detached. By palpation of the walls of the bladder I then discovered a tumor in the peritoneal cavity, close to the right side of the bladder, and about at the height of the fundus. The abdominal wall was incised directly over this tumor, which was found to be attached by a small pedicle to the omentum. It consisted of two ovoid masses, each about the size of a chicken's egg, and agglutinated to each other with their long axes at right angles. After the removal of this mass the palpating finger again detected the presence of some tumors lying closely together in the right iliac fossa. As these tumors could not be removed through the same opening in the abdominal wall, and the patient was thought to be too weak to be subjected to any more prolonged surgical operation, further proceedings were postponed to a more favorable time. The bladder was closed by a treble row of catgut-sutures, the first row uniting the muscularis and mucosa, the two following being seroso-serous. The incision through the abdominal wall was packed with iodoform-gauze, and three days later when there was no leakage of urine from the bladder, it was closed with silkworm-gut sutures. The other incision was closed after Olshausen's method. Irrigation of bladder and rectum continued as before. The perineal fistula was closing rapidly, and after two weeks no more urine was discharged through the rectum. The catheter had been removed from the boutonnière, and patient was able to void urine through the urethra. Temperature normal. Urine free from pus; general condition very much improved; appetite good. Three weeks after suprapubic cystotomy both openings into the bladder were perfectly closed, so that every drop of urine was passed through the natural outlet. Patient could hold the urine for about two hours. After another week's constant improvement in his general condition, patient was again placed on the operating-table for the removal of the remaining tumors. The abdominal wall was incised directly over the tumor which could under anesthesia be easily mapped out in the right iliac fossa. This tumor was found to be firmly adherent all around; it was extraperitoneal, but on that side which pointed toward the median line, it had encroached upon the peritoneum in such a way as to protrude into the peritoneal cavity. While attempting to detach it from the peritoneum this organ was torn. The accident, although unintentional, was no cause of regret, because through the opening thus made I was enabled to remove two other tumors, each about the size of a medium-sized orange, and about two-thirds the dimensions of the first one, which were more or less adherent to the omentum. By further digital exploration through the peritoneal opening I then discovered a large tumor, attached by a broad base to the lower surface of the liver, extending in its principal dimensions backward and upward. I incised the abdominal wall directly over the tumor and sutured it to the abdominal incision. Five days later the tumor was opened and evacuated; it contained about a quart of liquid and daughter-cysts, partly empty, partly filled. By means of a dull curette-like instrument, with a long handle, of which fully ten inches could be passed into the cavity in a latero-posterior direction, so much of the cyst-sac as could be reached was detached and washed out; the cavity was then stuffed with iodoform-gauze, and a liberal amount of absorbent cotton completed the dressing. On each following day this dressing was renewed after thoroughly irrigating the cavity. For about two weeks the washings brought out regularly small daughter-cysts and fragments of the cyst-sac; gradually these discharges diminished in quantity until finally the irrigating fluid was returned clear, still there was a little whitish discharge noticeable on removing the dressing. About six weeks after the operation the patient felt strong enough to leave the bed. Toward the end of December the fistula had closed, but it opened again after a week, discharged for about five days, and then closed definitely. The patient is now perfectly well and able to work at his trade. The case, apart from being very interesting from a pathological point of view, is highly instructive in a clinical sense.

Fortunately for the patient, but not for the interests of science, an autopsy was out of the question in this case, but nevertheless I think I can advance some very good reasons for corroborating the correctness of my views:

(1) The location of the tumor, which extended symmetrically from the central site of the prostate in all directions. (2) Perforation into the bladder took place at the lower end of the upper third of the prostatic portion of the urethra. (3) Relative incontinence of urine persisted for several months after the recto-vesical fistula as well as the suprapubic and median openings were closed. This relative incontinence proves that the sphincter vesicæ, which is found in the substance of the prostate, had been destroyed to a certain extent by sloughing caused by pressure, but was later regenerated.

The clinical lesson taught by this case is, that before resorting to the treatment of prostatic hypertrophy by castration, we ought to use the greatest care and circumspection in excluding all possible errors of diagnosis. Considering the clinical symptoms and history in this case, I felt justified in excluding carcinoma and tuberculous disease of the gland. I confess that the possibility of the presence of a hydatid cyst in that organ never presented itself to my mind. If it had, the character of the tumor might possibly have been determined by puncturing it and microscopically demonstrating the hooklets. In the absence of such evidence, if the withdrawn fluid be clear, containing no albumen, but a large percentage of sodium chlorid and succinic acid, the diagnosis of hydatid cysts will be sure.

The presence of albumen, uric-acid salts, and urea, does not refute the diagnosis of hydatid cysts, but in the absence of other conclusive proof the case will remain doubtful.

The cystoscope would have been useless in my case, for we cannot expect to make the contents of a cystic tumor, covered by thick, opaque walls, visible by the application of this instrument. There were no cysts attached to the walls of the bladder as was seen after suprapubic cystotomy had been done; it was only after rupture of the prostate that daughter-cysts found their way into the bladder and were discharged, thus leaving no doubt about the nature of the case.

Highly regretable as the useless mutilation of the patient in this instance necessarily must be, there is one element of consolation, which, of course, is of no scientific value, to be found in the fact that the patient is not worried by the loss of his sexual organs, and seems to be perfectly satisfied with his present condition.

I may mention, in this connection, as a noteworthy complication, that on the right side there was a hydrocele, containing about six ounces of fluid. The testicle of the right side was about twice as large as the one of the left, which was apparently only two-thirds, or less, of the normal size. Microscopic examination failed to show any structural changes in either of these organs.

The vesico-rectal fistula, in this case, must, in my opinion, have formed a triangle, with its base upward and the apex pointing down, so that a valve-like flap was formed, which afterward facilitated the healing-process considerably, so that after a week's duration no more leakage of urine into the rectum was perceptible.

It is a noteworthy fact that a liver-cyst of such dimensions as found in this case should not have caused any symptoms which would have led to an earlier diagnosis of its existence. The explanation for this is undoubtedly to be found in the peculiar location of the tumor, which could freely expand under the liver and behind the intestines, without compressing any vital organs in such a way as to interfere with their functions and thus to produce marked disturbances in the organism. The only symptom which might have enabled one to find the tumor was a feeling of fulness in the hypochondriac region, and of this the patient only informed me after the cyst had been evacuated.

AN ADDRESS.

THE HUXLEY LECTURE.[1]

BY PROFESSOR MICHAEL FOSTER, M.D.

THE lecturer began by stating that he proposed to make his lecture different in character from, and, as it were, a sort of preface to, those which would follow. It seemed fitting that this first lecture should take account of the condition of science in the day when Huxley took his seat as a student at the school of Charing-cross, as compared with its condition now; but the lecturer shrank from attempting any general survey of the progress of science, as affecting the profession, during the fifty years which had intervened.

The first theme was the special bearing on the profession of the advance of science, which became apparent from a survey of the studies of the medical student in the days of Huxley's studentship, and a comparison of these with the like studies of the present day. An examination of the schedule of compulsory studies issued by the Royal College of Surgeons in the early forties, showed that of the sciences ancillary or preparatory to medicine, no instruction was provided in physics, and very little in chemistry, that little coming in the middle of the student's course, and being instructed by lectures only. Of general biology, nothing was demanded by the College of Surgeons, save what incidentally came in Materia Medica, and only a little botany by the Company of Apothecaries. On the other hand, the greater part of each of the three years of study, right to the end of the course, was taken up by what was called anatomy and physiology, but was, in the main, human anatomy, which alone of the studies was taught practically—namely, in the dissecting-room.

The second theme was the complexity of the progress of science, and the intricacy of the bearings of even a single scientific observation. No one observation or experiment could be judged as it stood by itself alone. Its effects and so its worth would depend not alone or even chiefly on its own intrinsic merits, but also on the way in which it joined hands with its fellows. The bearings of a new truth could not be rightly expounded immediately on its birth; its value hung on that which went before, and its power rested on that which was to come. In illustration of this, the lecturer proposed to consider the bearings of some three or four physiological discover-

[1] Abstract of address delivered at Charing-cross Hospital Medical School, London, Eng., October 5, 1896.

ies, some three or four observations each the result of experiments on living animals made in the years of, or in those following closely upon, Huxley's studentship.

The first observation was made by the brothers Weber, in 1845, in Huxley's last year, in which they showed that electric stimulation of the vagus-nerve stopped the heart in diastole, or, as we now say, inhibited it. If the question were asked, What had been the gain of that experiment? the answer would be that its effects had gone far and wide into the whole of physiology, and thus into the whole of medicine, and, indeed, had not yet come to an end. It had enabled us to understand, and that more and more clearly as succeeding observations had illuminated the original one, how the heart is governed by the central nervous system, a matter which, before Weber's experiment, was merely the subject of fruitless contention, and which had shown us how we, too, might control it. It had become, in the hands of the physiologists, a method enabling them to solve problems which without its aid had baffled them. But perhaps its most far-reaching effects, and those which even to-day cannot be fully measured, lay in its having started a pregnant idea—that of regarding the phenomena of life as the outcome of opposing and antagonistic forces, now carefully balanced, now swaying on this side and on that, an idea which had been a guiding light, even if sometimes misused, in our advancing knowledge of the processes both of health and disease, not only in the tissues of the nervous system, but in all those of the body.

The next such observation to which the lecturer called attention was that by Claude Bernard, in 1851, when he showed that section of the cervical sympathetic led to fulness of the blood-vessels in the head and face. The same experiment had been made a century or so before, but dropped stillborn—the fulness of its time had not yet come. In Bernard's hand the experiment became the origin, the beginning, and so the cause of all that advance of physiological and medical knowledge which was indicated by the word "vaso-motor." There could be no need to dwell on how this knowledge had entered into and modified our conceptions of physiological and pathological events, general and special, or how, again and again, it came to the front in therapeutic endeavors. Yet, when Huxley was a student the very basis of that knowledge was not as yet assured; only the most advanced were prepared to admit that the blood-vessels had muscular walls. Bernard's experiment had its strength in Heule's histological demonstration, but had in turn been of such effect that could we draw from the web of the medical knowledge of to-day all that had come of it, that knowledge would become in a large measure a confused tangle—so much do we owe to one single experiment.

The lecturer next dwelt on Bernard's discovery in 1850 of glycogen. The effects of that one observation were again manifold. It had an immediate and direct effect on medicine in throwing light on that terrible disease diabetes, a light which, even if it had not fulfilled the hopes which were first held, had at least, by pointing the way toward alleviation, saved much suffering and greatly prolonged valuable life. But this had been only one and not the greatest of its effects. It had had the most powerful influence as the mother of ideas. It was the first clear direct proof of the synthetic powers of the animal body, and as such had been the parent of the great additions to knowledge, more especially in these latter days. But its chief influence had been, perhaps, that by showing how a tissue in a hidden way profoundly affected the blood, apart from any visible event, such as an outward blow, of secretion-fluid, or a muscular contraction, or a nervous impulse. It was the first exemplar of what we now call "internal secretion." Bernard's experiment had the relation of a father to a son toward all those researches on the thyroid and other organs which in our day had thrown so much light on the inner workings of the body, and added such powerful weapons to the medical armory; and, further, doubling, so to speak, on itself, had led us to a knowledge of the work of the pancreas, in the story of sugar, a knowledge which had cleared up much and promised still more.

The last illustration taken was Waller's observations in 1850 and 1852 on the dependence of the nutrition of a nerve-fiber on its continuity with the body of the nerve-cell of which it is a process. This discovery, also the direct gain of experiments on animals, was in itself alone of value as a contribution to our knowledge of the influences which the central parts of a cell surrounding the nucleus exert on other parts of the cell, and perhaps we did not as yet fully realize all that the observation taught. A still greater effect, however, on the progress of physiology and of medicine had resulted from the guidance and support which it had given to the experimental results of stimulating the cerebral cortex, an effect which yet another result, that gained by the application of the silver-method to the histology of the nervous system, was converting into an advance of knowledge of momentous importance. So far as could be seen, the Wallerian degeneration by itself, the experimental results of stimulation by themselves without anatomical support, and the results of the silver-method by themselves, would each of them have gone but very little way; the union of the three had produced, and was producing, a movement of theoretical and practical advance, whose limits could not be foreseen.

The lecturer concluded by a few words concerning the influence exerted by Huxley on physiology and so on medicine. Debarred by circumstances from fulfilling his early desire to become a physiologist, Huxley was ever ready with a helping hand to others. If English physiology stood at the present day, as it appeared to do, in a sound and hopeful position, that was in large measure due to Huxley's direct and indirect influence.

CLINICAL LECTURE.

TUBERCULOSIS OF BREAST AND LYMPH-NODES.[1]

By ROSWELL PARK, A.M., M.D.,
of Buffalo, N. Y.;
Professor of Surgery, University of Buffalo.

This little girl, twelve years of age, has not been well since she was vaccinated, four or five years ago. She

[1] Clinical Lecture at Buffalo General Hospital, Sept. 16, 1896.

shows a large scar on the arm, and her father states that the arm was very sore at the time of vaccination. There is no particular reason, however, to connect her present trouble with the vaccination. The principal complaint at present is of soreness in the right breast. The breast is much reddened, but this appearance is due to counter-irritants that have been used. On either side of the right axilla there is a chain of enlarged lymph-nodes, and there is a swelling in the breast that is tender on pressure. The child has not yet begun to menstruate, though her age suggests that with pelvic changes there may also be a development of glandular tissue in the breast. Sometimes, with approaching puberty, there will be tenderness and pain in the breast and, perhaps, a feeling of fulness, but not an actual tumor, such as is here present. The child has had two of the exanthems—measles and small-pox—each in quite a severe form.

We may exclude a physiological adenoma. There is no suspicion in my mind of malignancy, on account of the early age of the patient. One thinks, naturally, of tuberculosis, which, I believe, involves the mammary gland as often as it does any secreting gland, although tuberculosis of the breast is not often referred to in the text-books. There is also an involvement of the cervical and axillary lymph-nodes. In what tissue of the body the disease was primary, I do not know.

I do not advise operation at present, but I do advise the saturation of the system with those substances which have an antidotal power against the virus of tuberculosis. The physician in charge has been using an application containing ichthyol, of which I am quite fond. The ointment has also contained belladonna, and, as a result of this treatment, the breast is less tender. I often use an ointment of the following formula:

℞	Resorcini	5 parts
	Ichthyol	10 "
	Ung. Hydrargyri	35 "
	Lanolini	50 "

I should advise also the internal administration of guaiacol or of benzosol, in 25-centigram doses, t. i. d. I have seen great improvement follow the administration of this drug in many cases, especially in growing children. The hypodermatic use of tuberculin may also be of advantage. Plenty of fresh air, exercise, and freedom from school-life should be insisted upon. Cases of this nature have been apparently cured, and there is every reason to expect improvement from this line of treatment.

Here is another example of tubercular disease affecting the lymphatic system. This young man of twenty-one has noticed an enlargement of the neck for about a year. You can see the enormous mass, as large as my fist, on the right side of the jaw, while on the other side smaller nodes can be felt, from the size of a pea to that of a robin's egg. The family history is negative, the father dying of an accident and the mother being alive and in good health. In such a case of lymphatic enlargement, we should naturally look for possible sources of infection. In the throat are simply the evidences of mild chronic catarrhal pharyngitis, amygdalitis, etc. The teeth are in better condition than those of many patients whom we see in the hospital. There is no history of previous illness, running from the ears, nor eruption on the head. From any of these sources, infection of the lymphatics of the neck might follow. Especially in young children we may get a history of eczema of the scalp going on to ulceration and followed by involvement of the cervical lymphatics.

I have no hesitation in pronouncing this a case of tuberculosis of the lymphatics. The patient came to be cured, and is prepared to submit to operation. One might say off-hand that these masses are outside the large vessels, and that there is nothing that might not be removed with safety. On examining more carefully, however, I find a large mass in the right axilla and a smaller one in the left. There are undoubtedly tuberculous lymphatics beneath the pectoralis minor and the clavicle connecting those that are palpable above and below. While it would be possible by one, or better, by two long and severe operations to clear out these foci on the right side, there would still remain the lymphatics of the left side, and perhaps others of which we have no knowledge, but which would serve to propagate the tubercular disease. My advice, therefore, is to put the patient on about the same line of treatment as was indicated in the last case. The boy has already had his first injection of tuberculin, and as a result his temperature, which was normal two hours ago, has risen to 100.

Will it be possible to eliminate this disease entirely? I scarcely hope so, but it will undoubtedly be delayed, and the size of the masses will be diminished. In all cases of tuberculosis in which the disease is accessible and strictly limited I believe in operating, but even in local trouble, if the disease be so diffused that we cannot expect to eradicate it, operation is usually disappointing, a nidus for further infection being almost inevitably left behind.

The injections of tuberculin should not be made immediately into the affected area, because an additional amount of adhesion and infiltration will be produced. We must bear in mind the possibility of a demand for operative interference later. There is a little tenderness and redness over the largest mass, and if suppuration occurs the abscess must be opened.

MEDICAL PROGRESS.

Symptoms Produced by the X-ray.—PARKER reports, in the *New Orleans Med. and Surg. Jour.*, September, 1896, the case of a man who was shot in the lower jaw, the bullet passing through the left ramus and injuring the tongue. There was pain on the right side of the face, but the bullet was not found. Four days later an abscess on the right side ruptured into the mouth. He recovered promptly, and had no further symptoms until three weeks later, when for twenty minutes he was exposed to the X-ray. No trace of the bullet was obtained on the plate, and on alternate days he was again exposed to the influence of the rays for periods of time up to one hour and twenty minutes. There were five exposures in all, and no trace of the bullet was obtained. On each occa-

sion, on the day following the exposure, there were the local and general symptoms of inflammation, more marked after the long exposures, and subsiding only partially in a few hours. Two surgeons insisted that an abscess was forming, but after the X-ray tests were abandoned the swelling and pain rapidly disappeared, and did not recur.

LECERCLE (*Gaz. hebdom. de Med. et de Chir.*, September 24, 1896) has noticed in rabbits an increased elimination of phosphates by the kidneys, after the animals were exposed to the influence of the X-ray for three hours. This increase in phosphates continued for two days only.

A Triumph of Peristalsis.—RUNGE, in the *Bost. Med. and Surg. Jour.*, 1896, vol. cxxxv, p. 110, narrates an instance occurring in an insane asylum, which is deserving of a place among the remarkable feats of peristaltic action. A patient, suffering with melancholia, refused to eat, and was fed by means of a stomach-tube. As he soon acquired the habit of regurgitating the whole feeding, he became so emaciated that he never left his bed. One day the attendant came in to feed him, placed the tube on the window-sill, and stepped outside. On his return, half of the tube was missing, and the most careful search failed to reveal its whereabouts. One month later, a watery diarrhea which it set up was terminated by the extraction of the tube from the rectum. The piece swallowed measured 22½ inches.

A Simple Method of Diagnosing Diabetic Blood.—WILLIAMSON, in the *Brit. Med. Jour.*, vol. ii, 1896, p. 731, gives a simple method for making a diagnosis of diabetes by examination of a drop of blood. The amount of grape-sugar in normal blood is from .05 per cent. to .15 per cent., while in diabetes it is increased to from .27 per cent. to .57 per cent. This increase, slight though it is, has a distinctly increased power of decolorization of alkaline methyl-blue, as can be shown by the following test:

In a small, narrow, clean test-tube are placed 40 c.mm. of distilled water. A graduated capillary tube, such as is supplied with Gower's hemoglobinometer, is necessary for this purpose. The tip of the patient's finger is cleaned, dried and pricked, and from the exuding drop of blood 20 c.mm. are sucked up into the capillary tube and blown gently into the water at the bottom of the test-tube. Then 1 c.cm. of a watery solution of methyl-blue, 1–6000, is added, and finally 40 c.mm. of liquor potassæ, and the contents are mixed by shaking. A control-experiment is performed with non-diabetic blood.

The fluid in each tube is of a fairly deep blue. Both are placed in a glass containing water, and this is heated and allowed to boil for about four minutes. The fluid containing diabetic blood changes to a dirty, pale yellow, almost the color of normal urine. The other fluid becomes a bluish green or pale violet, but never loses its blueness. The tubes must be kept still while in the water-bath, as, if shaken, the methyl-blue is oxidized by the air, and may regain a blue tint. This is also the reason why a water-bath must be used for the boiling.

Taylor has applied this test thirty times in six cases of diabetes mellitus, and the decolorization was each time obtained. In 160 examinations made with the blood from healthy patients and from those affected with divers diseases, the decolorization did not once take place.

Trional vs. Sulfonal.—VON MERING has been conducting extensive experiments with trional upon man and the lower animals. His report, together with abstracts of the clinical results obtained with trional by sixteen other professors in as many different cities, is published in the *Therapeut. Monatshefte*, August, 1896. Von Mering himself administered it in almost one thousand instances. In some cases the patient took from 15 to 25 grains every second or third day for three or four months, without experiencing any discomfort. The testimony of the other sixteen professors was similar to his own. All stated that it was a more powerful hypnotic than sulfonal, and free from the unpleasant symptoms which sometimes follow the ingestion of sulfonal. Experience has proved that it is rarely necessary to give more than 15 grains of trional—at most 20 grains—in cases of uncomplicated sleeplessness. A feeling of drowsiness on the following day is proof that too much was given. In cases of sleeplessness due to pain, it works very well in combination with $\frac{1}{10}$ grain of morphin. If, for any reason, it is necessary to give a hypnotic daily for a long time, it is advisable to change the medicine from time to time, substituting occasionally for the trional, amyl hydrate, chloral hydrate, or chloralamid.

A Urethro-rectal Fistula.—BEACH of Pittsburg, Pa., in the *Med. and Surg. Reporter* of September 19, 1896, mentions an instance of that rare condition, a urethro-rectal fistula in the male. It occurred as the result of a perineal lithotomy when the patient was nine years of age. For forty-four years he went about in this condition, occasionally passing small amounts of urine per rectum and gas and feces per urethram. With a sound in the urethra and a rectal speculum, Beach easily demonstrated the presence of a fistulous tract between the two, large enough to admit the finger. A plastic operation was performed to close it, two flaps being taken from the mucous membrane of the rectum for that purpose. A silver catheter and rectal tube were left in position for ten days. The operation was apparently successful, but some months later gas appeared in the urethra and urine in the rectum, and examination showed that the fistula was only partially closed. A second operation will be undertaken to complete it.

Tracheotomy-tubes in the Air-passages—Treatment.—From the study of nineteen cases in which a tracheotomy-tube slipped into the lower air-passage, BILLOT (*An. des Mal de l'Or. du Lar. du Nez, Mar.*, '96) draws the conclusion that the presence of the tube is not immediately exceedingly irritating, so that the extraction need not take place at once, but still no more time should be lost than is necessary to obtain suitable instruments. If attempts to extract the tube with the means at hand fail, the patient should be encouraged to breathe deeply. The wound should be held open, or another large cannula may be introduced until preparations for the extraction of the old tube are completed.

On the Suprarenal Capsules in Addison's Disease.—RISPAL (*de Toulouse*) in the *Gazette hebdomadaire de Médecine et de Chirurgie*, August 27, 1896, speaks of the rarity of the absence of the suprarenal capsules in Addison's disease. He knows of but three cases: One reported by Kent Spender, the second by Fletcher, and the third reported by himself, which is as follows: The patient was a man, twenty-four years of age, suffering from Addison's disease, from which he died after ten months' illness. The autopsy showed that both suprarenal capsules were missing; also that there was no destruction whatever of the ganglions of the abdominal sympathetic nervous system.

Hard Chancre of the Eyelid.—ROHMCER, in the *Gazette hebdomadaire de Médecine et de Chirurgie*, August 6, 1896, presents a patient, thirty-five years of age, who, for three weeks, has been treated at the clinic of ophthalmology for a hard chancre of the eyelid. The trouble began by a small ulceration, situated on the inferior lacrimal point. This ulceration soon extended to the inner angle of the eyelids. Intravenous injections of cyanus of mercury (1-100) succeeded in curing the lesion in about a month. There was no enlargement of the preauriculary ganglion, and it was only after the fourth week that a slight enlargement of the submaxillary ganglion could be felt. About this time appeared also a very characteristic roseola.

On Fractures of the Femur Caused by Twisting.—In the *Berliner Klin. Wochenschrift*, August 31, 1896, TILLMANN reports five cases of fracture of the femur, caused by twisting the thigh. The violence seemed to him insufficient, and led him to an investigation of the subject, with most interesting results. In four cases the thigh was broken in the attempt to remove the boot, and in the remaining case the movement was the same, as the thigh was broken while the patient—a young man—was examining a wound in the sole of his foot. Three of the patients were men, aged nineteen, thirty-seven, and forty-eight; and two were women, twenty-seven and thirty-six years old. The man of forty-eight years died as a result of his injury. He had suffered for ten years from tabes dorsalis, while the woman of thirty-six years had shown the symptoms of this disease for two years. It is reasonable to suppose that the femur was weakened in these two patients by this disease, a possibility pointed out by Weir Mitchell in 1873. Charcot says that four per cent. of tabes-dorsalis patients present trophic disturbance of the bones. The other three patients were carefully examined, but they gave no symptoms either of tabes dorsalis or of any other disease which would account for a reduced strength of the femur. Messerer has shown that although a femur requires from 700 to 1000 pounds' pressure to cause it to break by bending, its shaft will give way under a twisting force of from eighty to 300 pounds, a force which is far too small to break off the head of the bone or to tear apart the ligaments at the knee or hip. Tillman attempted to verify these statements upon the cadaver, but he was able to break the femur by twisting in only seven instances. Two of these occurred in children of six and eight years of age, and the others were all in cadavers over sixty years of age. In the other subjects, owing to decomposition, the ligaments at hip and knee gave way. Dissatisfied, therefore, with the results, he looked up the three patients in whom fracture of the femur had no explanation, and at intervals since the accident of eight, five, and three and one-half years respectively, he found every one presenting well-marked symptoms of tabes dorsalis.

THERAPEUTIC NOTES.

For Pruritus.—SAVILL, in the *Brit. Med. Jour.*, September 19, 1896, mentions the good results which he has been able to obtain with calcium chlorid in the most obstinate cases of pruritus. At least 20 grains three times a day are required, and possibly twice that dose, but if given after meals, in a wine-glass of water, it does not disturb the stomach. To conceal its salt taste, it may be administered with a dram of the tincture of orange-peel and an ounce of chloroform-water. The remedy should be continued for two or three weeks after all symptoms have disappeared, and then diminished gradually, and not suddenly discontinued.

Glycero-phosphate in Sciatica.—Solutions prepared according to the following formulæ (*Gaz. heb. de Méd. et de Chir.*, September 13, 1896) are used by BILLARD with great success in sciatica:

℞	Glycero-phosphatis . . .	gram 5
	Aqua distil.	" 25

or

℞	Calcii glycero-phosphatis . .	gram 1.0
	Magnesii " . .	" 1.0
	Potassi " . .	" 1.0
	Sodii " . .	" 3.25
	Aqua distil.	" 25.0

The advantage of these concentrated solutions is in the fact that they keep indefinitely, while a weak solution will decompose. The solution should be put up in small tubes or vials, containing 2 c.cm each, so that fresh fluid may be used for each injection. From 1 to 2, or even 4 c.cm. are injected, under careful asepsis, in the seat of the pain. The effect is an almost immediate relief of the pain at the point of injection. In recent neuralgias, a single injection may suffice to bring about a cure. In more chronic cases, as in chronic sciatica, it is necessary to repeat the injection daily for a considerable time, and in some cases no lasting benefit is noticed. These injections are absolutely harmless, and usually produce no disturbance at the point of injection. The action of the drugs injected is not simply a local one, but they have also a beneficent influence upon the general nervous system.

Injection of Zinc Chlorid for Local Tuberculosis.—ZIEMATZKY (*Rev. de Chir.*, August, 1896) has employed the treatment recommended by Lannelongue in forty cases of tuberculosis of bone. He uses a ten-per-cent. solution of chlorid of zinc in distilled water, an ordinary syringe, and a rather long needle. As the object is to

make the injections subperiosteal, or at least under the ligaments, only a very small quantity is expelled in one place, the needle is withdrawn and another puncture is made. From twelve to twenty punctures are made at one treatment, from 10 to 15 grs. of the solution being employed. It is important that none of the fluid ooze out of the puncture, as the resulting necrosis is likely to form a sinus. This treatment is to be repeated every week.

Of seventeen cases in which the injections were begun in the incipient stage, twelve were completely cured by the injections. If an area of suppuration exists it must be drained and washed before injection, and advanced cases are unsuitable for injection. It goes without saying that important structures including bursæ and joints are to be avoided, and the needle should touch, but not penetrate, the bone itself. The action of the chlorid of zinc is, in Ziematzky's opinion, a germicidal one. Its evident result is first a leucocytosis and then a cicatricial formation.

Celluloid Plates for Flatfoot.—Instead of the usual steel supports for the arch made use of in flatfoot, KIRSCH (*Centralblatt f. Chir.*, No. 35, 1896) has used with great satisfaction a similar support made of sheet celluloid. The usual mold of the arch of the foot is taken, and a plaster model cast in this and shaved away, so as to make a slightly corrected representation of the patient's foot. Over this a sheet of celluloid of the proper size is bent and held in position by means of a towel. Model and celluloid are placed for one minute in boiling water, the towel twisted more tightly if necessary, and the celluloid allowed to cool. Its under surface is roughened so as to prevent slipping in the shoe.

For children, the plate of celluloid should be 1½ mm., for adults, 3–4 mm. (⅛ of an inch) in thickness.

The advantages of this support are its comfort and the ease and readiness with which it can be prepared.

Treatment of Diseases of the Respiratory Organs by Hot Baths.—LEMOINE in the *Gaz. hebdom. de Méd. et de Chir.*, August 27, 1896, speaks of the efficacy of hot baths in diseases of the respiratory organs. He proceeds in the following manner: If the case is very severe and the temperature high, he orders the baths every three hours, otherwise they are given whenever the temperature reaches 102.5° F. In all cases he gives regularly two baths during the forenoon and one during the evening.

The temperature of the bath varies from 95 to 98° F., the patient remains in from five to ten minutes. During the entire duration of the bath, the patient has a cold compress applied to the head, and on being taken out of the bath is rolled in a blanket and made to drink either coffee or grog.

The baths should be ordered in cases of simple bronchitis, capillary bronchitis, broncho-pneumonia, and pneumonia, no matter in what stage of the disease the patient is found. If the case is very grave it is better to begin with a mustard-bath of shorter duration, long enough to redden well the skin. This mustard-bath (if ordered) can only be repeated once during the twenty-four hours, the rest of the time the ordinary hot baths are given. The effects of the bath are very rapid, and it is seldom that they have to be given after the third day. After the first bath, generally, the temperature falls a little, the patient breathes better and is more calm, and later the lungs begin to clear. The baths seem to have a beneficial effect on the nervous system, on the functions of the skin, on the kidneys, and temperature.

Use of Picric Acid in Case of Burns.—PAPAZOLONGO in the *Journal de Médecine*, August 30, 1896, advises the following formula in the case of burns:

℞	Picric acid	5 grams.
	Alcohol (ninety per cent.) . .	50 "
	Distilled water	1000 "

This solution is employed in the following manner: If the burn is very extensive, put the patient, without being undressed, in a picric-acid bath, by so doing there will be less pain when the clothes are removed.

If the burn is limited, begin by washing the burned surface with the above solution; open the blisters to let out whatever serosity there may be, leaving the epidermis in place. After this proceed with the dressing; first put on pieces of sterilized gauze which have been soaked in the picric-acid solution, then cover this with cotton, which is kept in place by a bandage. It is better not to cover the dressing with oil-silk, etc., for this keeps the wound moist, and prevents cicatrization. This dressing is left in place three to four days, when it is replaced by a similar one which is left five or six days. In redressing the wound, if the bandage sticks, moisten it with the picric-acid solution. Burns of the second or third degree heal with two or three dressings, the cicatrix obtained is smooth and supple.

Constant Irrigation in Septic Puerperal Cases.—In the *Journal de Médecine Militaire*, p. 360, 1896, GLIAKOFF describes a method of treatment of puerperal cases by constant irrigation with solutions of carbolic acid and permanganate of potash. A one-per-cent. solution of carbolic acid was first employed, and followed by a weak solution (rose-colored) of permanganate of potash. The irrigating fluid was kept at 104° F., and allowed to flow for six hours. The results were excellent. Only one patient of the twenty-eight thus treated died, and she was not treated until three weeks after labor, and had pyemia. The analgesic effect of the irrigation was marked.

Treatment of Temporo-maxillary Ankylosis.—Two years ago HELFERICH (*Arch. prov. de Chir.*, vol. v, p. 125) recommended the resection of the head of the bone in temporo-maxillary ankylosis, and the interposition by a bit of muscle to prevent deformation of osseous tissue. ROCHET has followed this plan with success in three cases, though instead of resecting the head of the bone—a tedious operation and likely to be followed by facial paralysis—he removes from the neck, just below the head, a trapezoidal piece of bone, and introduces two muscular slips from the masseter, one in front and one behind, stitching them to the internal pterygoid muscle to keep the ends of bone apart.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

PUBLIC BATHS AND PUBLIC-COMFORT STATIONS FOR NEW YORK CITY.

COMPLAINT has frequently been made regarding the supineness and bad management of the officials of New York regarding baths and stations for public comfort. Lately, the *Independent* has returned to the charge and indicates that the work must all be done over again, beginning with new legislation at Albany.

A law was passed March 25, 1896, authorizing the appropriation of $200,000 for public baths in this city. The appropriation is excellent; but there are certain grave defects in the bill, because it does not provide for the purchase of any property for the location of public baths; they are to be erected in the public parks. The error of this provision was evidenced by the strong local feeling in opposition to a bath in Tompkins square. Again, the baths should not be free, a conclusion which is confirmed by the practice of English and Continental cities. While the city should build them, those using them should pay for that privilege. The most important defect in the bill is the way in which responsibility is divided.

According to the law, the Department of Public Works is to build the baths, and in case any of them should be located in parks, the Department of Public Parks is to exercise control over them. The operation of a public bath is solely a matter of public health and sanitation, and there is again no reason for departing from the previous practice, which placed them under the control and supervision of sanitary authorities, which in New York would be the Health Department. It is rather a common practice with the English municipalities to make a bath-establishment a common place of meeting for the members of a parish for recreation and improvement.

The proper provision of public-comfort stations is axiomatic, and the lack of these conveniences is a disgrace to American cities and towns, and New York in particular. On July 5, 1895, an Advisory Committee was appointed by Mayor Strong to take this subject under advisement, and to report at once some means for carrying out recommendations of the Sub-Committee, appointed by the Committee of Seventy on Public Baths and Lavatories. It is now more than a year since that appointment, and nothing has been done. When will the Mayor's Committee emerge from their cloistered seclusion with a few practical suggestions? It may be, however, that advice has already been proffered by them, and not accepted by the Mayor.

THE PREVENTION OF CHOLERA IN INDIA AND THE ERECTION OF A LOCAL PASTEUR INSTITUTE.

MR. ERNEST HART, the distinguished editor of the *British Medical Journal*, in a recent letter has given a most interesting and instructive account of the evolution of vaccination against cholera. Incidentally he also presented a brief but fascinating sketch of the life of Haffkine to whom most of the credit is due for all that is known in this promising branch of preventive medicine. That these discoveries are not accidental, but rather the results of well-planned research on the part of minds especially adapted for such work by both nature and education, is manifest in the fact that Pasteur, when requested by the king of Siam to furnish an antidote for cholera, turned at once confidently to this young man to undertake

the task. At this time (1891) Haffkine was professor of physiology at Geneva.

Any investigation along this line seemed hopelessly blocked in the very beginning by a natural immunity of all lower animals to the infection of human cholera. But it was not long before an acquired susceptibility was induced in rabbits. The next difficulty encountered was that the intensified or "exalted" virus produced such active local inflammation that sloughing at the site of injections was the invariable result. But this, too, was finally overcome by the discovery that in using preliminary inoculations of the attenuated virus the system could be so prepared as to obviate entirely the local irritation. Early in 1893 the method was tried by Haffkine upon himself and some fifty courageous volunteers with the positive confirmation of its safety. It is a notable fact that up to the present time 70,000 vaccinations have been made upon 42,000 individuals without an accident of any kind. After demonstrations of his method in Paris, and in London before the Royal College of Physicians and Surgeons, Haffkine was allowed to proceed to Bengal where his mission received active interest and support from the Indian authorities. The magnitude of his undertaking, as well as the urgent need for succor from some source, requires no further emphasis when we consider the many thousands of human lives surrendered to this insatiable enemy of mankind in tropical Asia. An interesting feature that contributed greatly to the success of the experiment is the fact that the natives, instead of opposing this procedure, looked upon it as a revival of a traditional practice among their early religious teachers, and accepted it with alacrity.

In April, 1893, Haffkine began work in those regions of India where the disease is endemic, and for twenty-nine months inoculated all classes and conditions of men to the number of 11,000.

The result of these investigations justifies the statement that the vaccinated are twenty times safer from the disease than the unvaccinated, and eighteen times securer from death. The effects are of such a manifestly promising character that steps are being rapidly taken to establish a local Pasteur Institute. *The Indian Medical Record* states that the government of India has offered 5000 rupees annually toward its support, and 10,000 toward its erection, with the following provisions: (*a*) That competent vaccinators are provided to deal with outbreaks of cholera, and to inoculate coolies recruited for the tea gardens; (*b*) to inoculate hydrophobia-patients; (*c*) to give instruction in practical bacteriology. The national tea- and mining associations are expected to contribute liberally to the erection and support of the institution.

THE TREATMENT OF HEMORRHOIDS.

Where a large number of different surgical procedures are recommended to cure a certain condition, it is apt to mean unsatisfactory results. This is not true, however, in regard to the cure of hemorrhoids. The surgical treatment of this condition dates back to the earlier centuries, and some of the newer methods differ but slightly from those recommended fifty years ago. The operations which the last decade has brought forth, however, notably that of Whitehead and its many modifications, have taken a prominent position in the treatment of hemorrhoids.

During the past twenty-five years there have been much discussion and difference of opinion concerning both the major and minor operations for the cure of this condition. Whether or not the injection into the pile of diluted carbolic-acid, alcohol, or other solutions, is a safe and reliable plan of treatment, is a question which as yet has not been satisfactorily answered. The popularity and undoubted success of this method of treatment among quacks certainly indicates that it possesses some virtue. While occasionally disagreeable results follow such injections, and while frequently cure does not result, yet it must be granted that in many cases relief is obtained. It is suitable for a limited number of cases only.

Of the major procedures the three methods which are generally adopted are the ligature, the clamp and cautery, and the Whitehead operation. Each one of these gives excellent results, and it is difficult to decide which one will give the best results in the greatest number of patients. It is true that many a surgeon will favor a certain method. He adopts it in a large number of cases; his results are good; he learns from constant

practice to perform it very skilfully; he becomes prejudiced in its favor, and finally, claiming superiority for his particular procedure, adopts it for all his patients, a certain number of which could preferably be treated by one of the other methods were its details as perfectly carried out by him as are those of his "pet" operation. The operative treatment of hemorrhoids affords one of the best illustrations of this rather warped state of mind. One authority claims that incomparably better results are obtained after the ligature-operation than after the employment of the clamp and cautery. Another authority of equal distinction claims that the clamp and cautery-method is superior to all others, and that he makes use of this method exclusively. The advocates of Whitehead's method have found it thoroughly satisfactory, though they advance their claims in a more modest manner. Probably this operation has received a greater share of abuse and severer condemnation than either of the others, and certainly more than it deserves. To the unprejudiced observer the plan of Mr. Whitehead is for certain cases the best of all. As a method for general use in all cases it is the worst.

It is true that a greater amount of technical skill is needed, that more blood is lost, and more time consumed than is the case with either of the other methods. With a practised surgeon and skilled assistants, however, these objections should not prevent the choice of this method in suitable cases. The ligature- and cautery-operations are simpler, and are certainly better adapted for general use. One method seems to be as commonly used as the other. The same advantages are claimed for each, and it must be granted that the results of either plan are in the majority of cases satisfactory.

The recent operations which have been proposed are generally modifications of the Whitehead-method. Variations of the old plan of excision are also from time to time introduced. The general tendency of these modifications is to remove the hemorrhoidal bunches, and at the same time not to cut away the mucous membrane from the entire circumference of the rectum, on the theory that the membrane lining the canal-outlet has functions to perform. Practically, these functions have never been satisfactorily demonstrated, but several interesting studies of this subject have been made, as for example the careful examinations and dissections of the anal mucous membrane by B. B. Stroud of Cornell University, who has found that in the mammalia there is a narrow zone of transitional epithelium between the skin and rectal mucosa, called the pecten, in which he claims are the peripheral ends of nerves concerned with a special rectal sense, and that also in some human individuals there are developed papillæ which he believes to be important additions to the "rectal-sense" apparatus. Other physiologists and surgeons have made the same claim and attribute the incontinence, which at times follows Whitehead's operation, to the removal of these terminal sensory nerves, though it is quite as probable that it is rather due to injury of the sphincter-muscle during the operation. In some of these modifications strips of the mucous membrane are left undisturbed, the piles with the overlying mucosa being excised between them. In others, as in the procedure advocated by Baumgartner at the last German Surgical Congress, the hemorrhoids are excised through a vertical incision in the mucous membrane and skin, the edges of which are afterward united. This, however, is practically the same method as was introduced by Quénu and others years ago. Other methods are of less importance.

In one sense it is rather unfortunate that there should be such diversity of opinion on this subject. The student and young surgeon are apt to be bewildered by such contradictory statements. They can feel assured, however, that either one of the three methods is safe and reliable, and is supported by authority of equally skilful rectal specialists. Experience must teach him the rest.

A. J. McCosh, M.D.

ECHOES AND NEWS.

Electric Heaters.—The German Hygienic Association offers a prize of $1200 for an essay containing original research upon the efficiency of electric heaters for domestic purposes.

A Classification of Skin-diseases.—John Hunter divided skin-diseases into three classes: Those which are cured by

sulfur; those which are cured by mercury; and those which the devil himself could not cure.

Two Chinese Lepers Escape.—Long Dong and Sam Loo, Chinese lepers, who had been confined in the leprosy-ward in the hospital on North Brother Island, New York, for nearly one year, escaped on the night of October 28th.

Serum-therapy in Pulmonary Phthisis.—Régnier in an "Essay on Serum-therapy in Pulmonary Phthisis," by Maragliano's method, announces the results in 325 cases as follows: Stationary, 50; improving, 140; good results, 45; no results, 25; deaths, 14.

The Parasite of Whooping-cough.—Kurloff believes that the specific microörganism of whooping-cough is a protozoan. He has found uniformly in the fresh sputa of patients ameboid organisms with spherical spores characterized by concentric lamination.

Dr. Bolton's Resignation.—Dr. B. Meade Bolton has resigned the position of chief of the Municipal Bacteriological Department, Board of Health, Philadelphia, in order to take a professorship of bacteriology and pathology in the University of Missouri at Columbia, Mo.

A Roll of Honor.—A hall has been established in the Val de Grace Hospital in Paris where the names of French medical men who died in the performance of their duty are inscribed on marble tablets. A list of 143 practitioners has been placed on its walls, all of whom perished in the yellow-fever epidemic in San Domingo, 1801–1803. *Indian Medical Record.*

The Turin Institute.—During the first six months of 1896 345 persons bitten by dogs that were mad, or suspected of being so, presented themselves for preventive treatment at the Turin Institute. There were no deaths among the 229 that followed the Pasteur treatment. Since September, 1896, the date of the opening of the institute, 2895 persons have been treated by injections of the virus, and the death-rate has been 0.76 per cent.

The Plague in Bombay.—According to the Bombay newspapers the generally accepted theory of the outbreak of bubonic plague in the presidency is that the disease was imported from China, it having first appeared among the Lohanas, who are mostly employed on steamers trading with China. The plague caused great mortality among the rats before the inhabitants were aware of its presence, and this is probably confirmatory of the theory that these animals are the carriers of the infection.

Obituary.—James B. Murdock, M.D., late dean of the Western Pennsylvania Medical College, died October 29th at Bellefield, Pa. He was born at Glasgow, Scotland, in 1830. He was graduated from the College of Physicians and Surgeons, New York City, 1854. For a time Dr. Murdock practised medicine in Oswego, N. Y. He located in Pittsburg in 1877.—Professor H. Newell Martin died at Burley, England, October 27th. Professor Martin took the chair of biology at Johns Hopkins University in 1876, and served until 1893, when he was compelled to retire because of failing health. He studied with Huxley, and was by him recommended to the faculty of the university.—Dr. C. E. Brown-Séquard, the only son of the late Professor Brown-Séquard of Paris, France, died recently at the age of thirty years in Atlanta, Ga., where he was engaged in scientific work.

Sulfonal in the Night-sweats of Phthisis.—Combemale and Descheemacher, in the *Bull. med. du Nord*, record experiments with sulfonal in the night-sweats of phthisis. In the first and second stages of consumption, in some instances, sulfonal causes entire cessation of the sweating, in others the sweating is limited, especially to the head, while in others the sweating disappeared, but a slight moisture of the skin was noted. While complete stoppage of night-sweats is not always obtained, they are at least greatly modified.

The Use of Kidneys in Renal Diseases.—The Berlin correspondent of *The Medical Press* says: "Following the prevailing fashion of the day an ingenious Russian physician has for some time administered kidney in renal disease. The cases consisted of acute and chronic parenchymatous nephritis, granular and amyloid kidney. Increase of urinary secretion, diminution of albumin, and cessation of uremic symptoms were observed. After taking at least twenty kidneys the therapeutic effect was permanent, and the patients could be looked upon as cured. The kidneys were given fresh and in a raw state."

The Formation of Antitoxin by Electrolysis.—Marmier in *Annales de l'Institut Pasteur* describes a series of experiments to determine whether antitoxin can be obtained by electrolysis. He finds that with venin and with diphtheritic toxins he is able to obtain no attenuating effect with alternating currents of high frequency, but that with continuous currents there is a distinct attenuation of the virus to be noted. Continuous or alternating currents of low frequency destroy bacterial toxins, simply because they have the power of producing hypochlorites and chlorin from the chlorid of sodium dissolved in the solution of toxins, this substance in a nascent condition exerting a considerable effect upon the toxins.

Origin of Fat in the Body.—Kaufmann, in the *Archives de Physiologie*, gives the results of his experiments upon the origin of fat. His conclusions are as follows: The proteids, in common with the customary compounds of the food, contribute, though not exclusively, to the formation of fat. When, during digestion, there is absorption of a large quantity of proteids, they disintegrate and form fat. Of this, one part oxidizes and, passing through the glucose stage, supplies the physiological energy requisite for the organism; a second undergoes incomplete oxidation and is transformed into carbohydrate, which is stored up in reserve as glycogen; the third is deposited as fat. The proportion of fat deposited during digestion varies with the abundance of the repast, and the amount of glycogen in the organism. The whole of the non-oxidized fat may be converted into glycogen in an animal poor in that substance. Calorimetric investigations demonstrate that

the anaërobic decomposition of albumin, if it occurs, is not attended with any liberation of heat.

N. Y. State Association of Railway Surgeons.—The following is the program of the sixth annual meeting to be held in the Academy of Medicine, New York, Tuesday, November 17, 1896. Morning session, 9.30 sharp: (1) "Modern Methods in the Treatment of Fractures," Dr. R. H. Cowan, Radford, Va.; (2) "How can we best Secure Immobilization in Compound Fractures at or near Articular Processes?" Dr. Z. J. Lusk, Warsaw; (3) "Immobilization and the Treatment of Fractures at the Elbow-joint," Dr. J. H. Glass, Utica; (4) an address, "Injuries to the Head," Dr. Roswell Park, Buffalo; (5) "Relief and Hospital Department," Dr. Frank H. Baldwell, Waycross, Ga. Afternoon, 1.30 sharp, executive session: (6) President's address, Dr. C. S. Parkhill, Hornellsville; (7) "Traumatic Neurasthenia," Dr. J. E. Walker, Hornellsville; (8) "Cases of Apoplexy following Some Time After Accidents," Dr. William Browning, Brooklyn; (9) "Cranial Injuries," Dr. W. A. Ward, Conneaut, Ohio; (10) "Distinctive Features of Railway Surgery," Dr. R. S. Harnden, Waverly; (11) "Granulation-surfaces," Dr. John Van Duyn, Syracuse; (12) "Chloroform-anesthesia," Dr. Webb J. Kelly, Galion, Ohio; (13) "Injuries to the Eyeball," Dr. Samuel Mitchell, Hornellsville; (14) "Acute Infective Thecitis," Dr. A. Llewellyn Hall, Fair Haven, N. Y.; (15) "Compound Fracture of the Skull, with Injury to the Brain-substance, with report of cases," Dr. J. G. Kelly, Hornellsville. In the evening there will be a reception and banquet at the St. Cloud Hotel, in honor of the invited guests of the Society.

CORRESPONDENCE.

THE USE OF SURNAMES ONLY IN CITING AUTHORITIES IN MEDICAL LITERATURE.

To the Editor of THE MEDICAL NEWS:

DEAR SIR: Having been engaged lately in literary work involving considerable consultation of papers and verifying of references, I have realized, as any one must under the circumstances, the extra labor necessitated by a practise, which has always been more or less general with authors, of mentioning only the surnames of writers and investigators referred to. Any one who has had experience cannot fail to have been struck with the large number of persons of the same surname who are contributors to medical literature, so that a reference to Dr. Sydenham's or Dr. Jones' views, or Dr. Ranklin's papers, gives a very imperfect idea of the individuality of the author. Take, for example, the name Hoffman. The student will find, in the Surgeon-General's catalogue, this surname more than one hundred times, and, of these many Hoffmans, quite a number are authors of voluminous and important papers; so that to be told that Hoffman believes thus and so is of little assistance to the reader who desires to look up his views and papers. Again, to take a name to which modern medical literature often refers—Laveran. At least two Laverans, both army surgeons, have written papers of importance. The Laveran[1] whose name is so identified with the malaria plasmodium is A. Laveran, while Louis Laveran is a very different person; yet writers only quote Laveran. It is needless to multiply instances; they will occur to any one. My object in asking publicity for this letter is to beg writers to adopt the practice of giving the full name of the authority quoted. This, of course, involves a little trouble at first to hunt up the Christian name, but, as years roll on and we all are thus explicit in indicating authorities quoted, it will become easier and easier, while the amount of labor saved to those looking up references will be immeasurable. Especially important is it that the editors of the various hand-books and annuals, which are now filling such a useful niche in medical literature, should adopt the practise of using the full name, for it is from suggestions in such books that writers often want to look up references.

Respectfully yours,

JAMES TYSON.

PHILADELPHIA, PA.,
October 30, 1896.

SPECIAL ARTICLE.

PROGRESS AT CRAIG COLONY DURING THE EIGHT MONTHS SINCE THE OPENING.[2]

THIS has been the crucial year in the evolution of Craig Colony. All of the buildings, which were in the Shaker settlement at the time of its purchase for dependent epileptics by the State, have been thoroughly remodeled and put into complete order for the reception of patients. A perfect system of water-supply, sewerage, plumbing, heating, and electric lighting has been installed, and on February 1, 1896, the Colony was informally opened for patients. One hundred and forty-nine patients have been received thus far, and as soon as the hospital building, now in course of construction, is completed, and the west group of buildings heated, the accommodations of the plant, as it now stands, will be ready for a population of over two hundred epileptics.

In spite of the shortness of the time now elapsed since the opening of the Colony, two very important facts have become evident: (1) that remarkable improvement has taken place in the condition of the patients admitted, and (2) that the economic success of the scheme is assured.

EFFECT OF COLONY-LIFE ON THE PATIENTS.

Nearly every case has gained in weight and in general health. In all cases the epileptic seizures have diminished in frequency to a marked degree, and in some instances this has been even extraordinary. The expression of the inmates has altered, so that instead of the dull, hopeless look of the almshouse epileptic, one sees on all sides happy faces in which intelligence and hope are being reawakened.

The school has been successfully started for fifteen or

[1] Unfortunately, even the Surgeon-General's catalogue has not the full Christian name.

[2] Official report of the Medical Superintendent.

twenty of both sexes. Much of the printing of the colony is now done by two or three epileptics in the colony's own printing-office. Carpentry, sewing, painting, etc., are being carried on by the patients. They have their own epileptic blacksmith. Naturally the great work of the inmates of both sexes is in the field and garden. Eighty-three per cent. of the males and seventy-six per cent. of the females have given us eight hours' daily labor. This labor has had a great effect upon the income of the colony, demonstrating the

ECONOMIC VALUE OF THE SCHEME.

From the report of the superintendent and steward for the year ending September 30, 1896, we learn that the products of the farm and garden for the year 1896 amounted to $14,230.20. The cost of maintainance of patients from the date of opening, February 1, 1896, to October 1, 1896, a period of eight months, was $28,-258.24. The colony has therefore actually produced already one-half of the cost of maintenance.

Appropriations are asked for this year to increase the productivity of the agricultural department especially, because upon this the economic success of the scheme depends so largely.

At the same time there is most urgent need of accommodations for the hundreds of patients seeking admission. There are nearly a thousand patients still a public charge in the almshouses, insane asylums, and various charitable institutions, who nced to be provided for at Craig Colony. The managers will ask the Legislature to provide this coming year dormitory accommodations for at least three hundred more patients.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting October 6, 1896.

B. ONUF, M.D., read a paper entitled,

A CONTRIBUTION TO THE STUDY OF MOTOR APHASIA,

in which the following case of cortical motor aphasia was reported:

Mrs. S. D——, twenty-three years of age, had an attack of acute articular rheumatism three years ago, during which she probably acquired an endocarditis with valvular lesions of the heart. On June 7th, after a miscarriage, she had an attack of embolism, followed by hemiplegia of the right side, and involving the right arm, and particularly the hand and fingers. She said that the understanding of spoken language was unimpaired, but this statement should be taken with some allowance. He had first seen her on April 3d. At that time there was slight disturbance of motor speech—*i.e.*, slight difficulty in finding the words, and an occasional misuse of words, or an improper construction of sentences. She had difficulty in giving the name of common objects presented to her. Aside from these disturbances, there was marked defect of the faculty of reading and writing, individual letters of the alphabet being frequently mistaken. She found it, as a rule, easier to read the word *in toto*, than to spell it. The word "one," for example, was pronounced correctly, but spelt "won." In the writing, which was done with the left hand, the patient used printed characters, both in copying and writing from dictation. The auditory impressions received from loud reading undoubtedly helped her understanding, and enabled her to read words which she could not do otherwise. There were absolutely no other visual disturbances—no hemianopsis, and no narrowing of the visual fields. Apparently there were no gross lesions of memory.

He also reported the case of a man whose speech had been suddenly affected, so that he spoke very thickly, and could hardly be understood. There was no real aphasia, for he knew what he was going to say, and always succeeded in saying it, but the words were very much blurred. Five days later he died with symptoms of congestion of the lungs. On *post-mortem* examination, a blood-clot was found at the level of the lower part of the ascending frontal and ascending parietal convolutions of the left hemisphere. Almost all the cortical substance of these convolutions had been destroyed, but the third frontal convolution had been left intact.

It was easy to understand the occurrence of motor aphasia with alexia and agraphia, if we supposed that Broca's center was involved. This view found further support in the fact that many cases of motor aphasia with alexia had been reported, in which the aphasia had been almost entirely recovered from, while the alexia had remained. He could not answer, however, the question, why in this and many other cases there was an earlier recovery from aphasia than from alexia. The observations in this case would go to show that most of the words were read as a whole, and not by spelling. It was certainly not possible in the English language, because of the variety of ways in which certain groups of letters are pronounced in different groups. In learning Russian, he had himself begun to read before he had been entirely familiar with the letters of the alphabet. Although to a certain degree he had read the language "spellingwise," he still recognized many words by familiar combination of letters, and by the sense. He believed that the reason his patient used printed characters solely was, that there was a loss of motor-graphic memories. The visual memories for printed signs are usually much better established than those for script, for the reason that reading is chiefly done from printed characters. That muscular sensations play a very important part is shown by the fact that we can write with the eyes shut. If we are warranted in speaking of a motor speech-center, we must be justified in speaking of a physiological apparatus in which muscular graphic memories are stored. Loss of these memories does not imply absolute impossibility to write, as visual memories may supply the deficiency. It is not supposed that the lesion may just destroy the motor-graphic memories and leave intact the other motor faculties connected with the hand- and finger-muscles. A patient with a lesion of Broca's center can understand what is said to him, but he has lost the power of inwardly repeating what has been said. The motor speech-center forms such an important factor in the evolution of the higher mental

processes, that its lesion cannot remain without damaging influence on the mental activity.

DR. JOSEPH COLLINS could not agree with Dr. Onuf that a person having pure motor aphasia, was completely unable to read. He had one patient who was completely aphasic, yet he could write prolifically, and was able to read understandingly both his own writings and those of others. He certainly both read and understood these writings. Hence, the speaker said he could not believe that with pure and complete motor aphasia there is necessarily alexia. He did not think there was any objection to subdividing the motor speech-center into an articulo-motor center, and placing adjacent to it the centers for phonation, labial movements, and buccal movements.

DR. B. SACHS had recently observed a case in which aphasia was the sole symptom of a cortical tumor. The manner in which it progressed would seem to justify fully the subdivision of the motor speech-center, and also to show that speech is not the function of any one center, or any series of centers, but that it is really the result of a very close union of these centers by distinct association-tracts. If this were not so, a relatively small lesion could not explain the variety of symptoms observed in the case which he reported. The patient was a lady who had been carefully observed by her brother, who was a physician. The first thing noticed was an apparent slight apathy, but this was really due to a difficulty in speech. When first seen by Dr. Sachs, about three months after this, it was found that she had lost the faculty of using nouns, so that she could not give the names of those persons best known to her. After a time the difficulty of speech became more distinct; there was great difficulty in finding words. Toward the end only was there a distinct deficiency in the understanding of language. From the very first her brother had noticed a distinct difficulty in reading, and a still greater difficulty in writing. He had never seen a patient able to speak so much and yet unable to name or even copy single letters. She could, however, write a *whole* name fairly well. Such a case seemed to show the necessity for a further subdivision of the motor-area. The paper of the evening was of value as a corroboration of Bianchi's views. It showed that we were gradually turning to larger divisions rather than to the small localization-areas, which we employed as a result of the teachings of Ferrier.

DR. ONUF, in closing the discussion, said that he distinguished two forms of aphasia—cortical and subcortical motor aphasia. The latter was also called pure motor aphasia. In cortical motor aphasia, it was assumed that the cortex, where psycho-motor images of speech are deposited, is affected. Subcortical aphasia is one in which there is an impossibility of loud speech, but internal language remains intact; hence, such persons can read and write perfectly. He believed the cases referred to by Dr. Collins were examples of subcortical motor aphasia.

G. W. JACOBY, M.D., read a paper on

THE COMMITMENT OF PATIENTS AND THE NEW INSANITY LAW.

Under the name of the insanity law there went into effect a new law in July of this year. In his opinion, the framers of the law had totally failed to unite the postulates of jurisprudence with those of medicine—indeed it would seem that they had intentionally ignored, as far as possible, the medical side of the subject. The medical certificate no longer serves for the temporary detention of the patient for five days. The responsibility for the commitment has been removed from the shoulders of the physicians to those of the judge, and a matter which is essentially medical has been transformed into one chiefly legal. This law also provides that at least one day before the physician presents his application to the judge, the patient is to be informed of the proceedings. This personal service can be omitted under certain circumstances, according to the discretion of the judge. After all the necessary legal preliminaries have been taken, the superintendent of the institution to which the patient is committed, may refuse to accept the patient on the ground that he does not consider the person insane, or that the papers are not made out properly. There is also a provision for an appeal from the decision of the judge and a trial by jury. The old law was much better, particularly on account of its provisions for temporary detention. The provision which takes away every method of procedure except appeal, when the application is refused, is a particularly objectionable feature. Personally, he would not be satisfied with an insanity law which would not allow of the temporary commitment of the person on the strength of medical certificates by two qualified physicians, one of whom should have special psychiatric qualifications.

DR. CARLOS F. MACDONALD said that he wished at the outset to disclaim any responsibility for the framing of the new law. It had its origin with a member of the Statutory Committee of Revision. He was the only physician in this State who had opposed the bill before the legislature. During the past seven years, as commisioner in lunacy, he had examined thousands of cases of alleged illegal commitment, and he had yet to learn of a single case of a sane person being committed through corrupt collusion and through intent, although he had occasionally known of instances of mistaken diagnosis, such as might occur in connection with any disease. He thought that, as a rule, judges would waive the notice of personal service upon the patient or friend, and it seemed to him a distinct advantage to make the commitment a judicial order, rather than a judicial approval, as in this way it relieved the medical profession of much responsibility and the danger of suits for damages. In his judgment, the weakest point was the absence of any provision for temporary detention. A determined effort should be made this winter by the medical profession to amend the law in that respect. Curiously enough, the laity consider themselves fully as qualified as physicians to diagnosticate insanity, and this new law is an outgrowth of that feeling.

DR. C. L. DANA said that his views were entirely in harmony with those of the reader of the paper, and the Society should make it clear that it appreciated the absurdities and many faults of the new law. It had caused an infinite amount of trouble to the city physicians, and the ordinary process of commitment had, in consequence,

become tedious and expensive—so much so that physicians had found it advisable to commit insane persons, as far as possible, to institutions outside of this State.

DR. HAMMOND then offered the following resolution, which was unanimously adopted:

RESOLVED, That the President appoint a committee of five to report to the Society such measures as it may deem expedient for securing the amendment of the present lunacy law, governing the commitment of the insane.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, September 9, 1896.

G. BETTON MASSEY, M.D., read a paper entitled

ELECTRICITY IN GYNECOLOGY AT THE HOWARD HOSPITAL.

The cases submitted to treatment were strictly gynecologic, the majority presenting evidences of chronic inflammation, exudation or hypertrophy of the pelvic organs, neoplasms, pathologic displacements or disturbed innervation, including certain neuroses with pelvic manifestations, and post-operative painful affections. Thirty cases of fibroid tumors of the uterus were treated. In one case a submucous tumor was expelled from the uterus by contractions induced by the electric current. Three tumors disappeared almost entirely by absorption. In eight cases there were symptomatic cure and great reduction in size. In eight other cases there were symptomatic cure and slight reduction in size. In two cases symptomatic cure resulted, without reduction in size. Four cases were yet under treatment, with a favorable outlook. Three cases failed to continue the treatment for a sufficiently long period. In only one case was there no improvement. No bad results attended the treatment, and practically no discomfort attended or followed the applications. Suppuration in the neighborhood of the tumor and cystic degeneration of the tumor contraindicate the local employment of electricity. Cystic degeneration is recognizable by palpation and suppuration, by the failure of the applications of the faradic current to relieve temporarily the pain and the aggravation of the pain by intra-uterine applications of galvanism. Of sixteen cases of chronic metritis, thirteen were cured, two improved, and one not improved. Of fourteen cases of perimetric inflammation, six were cured, six improved, and two not improved. Of four cases of chronic ovaritis, two were cured, and two improved. Of eight cases of post-operative pain and neuroses, one was entirely relieved, three improved, and four remained unimproved. One case of incipient, but undoubted, carcinoma of the breast was cured and has remained well. Two cases of carcinoma of the cervix were temporarily improved, while one remained unimproved. Other affections treated were: Subinvolution, 7 cases, all cured; menorrhalgia, 5 cases—4 cured, 1 improved; endometritis, 4 cases—3 cured, 1 improved; retroflexion, 2 cases—both improved; retroversion, 2 cases—1 cured, 1 improved; pyosalpinx, 2 cases—1 cured, 1 became worse; hydrosalpinx, 1 case—cured; ectopic gestation, 1 case—cured; prolapse, 1 case—improved; urethral caruncle, 1 case—cured; pruritus, 1 case—cured.

In reply to questions propounded in the discussion, Dr. Massey added that tuberculosis of the genitalia is a contraindication to the total employment of electricity; and that the cure in the case of ectopic pregnancy consisted in arresting the life of the fetus, followed by shrinking of the tumor, after rupture into the broad ligament.

JOHN LINDSAY, M.D., reported

A CASE OF PROSTATIC ABSCESS,

occurring without obvious cause in a married man, twenty-nine years old, a waiter. The patient was seized with chilliness and a feeling of soreness in the joints and muscles, together with general debility. The temperature was 101° F., and the tongue was coated. The case was treated as one of influenza, but improvement did not take place. The patient remarking casually that he had piles, rectal examination was made and disclosed general enlargement of the prostrate gland, together with local heat. The patient denied ever having suffered from urethritis, and there was no history of traumatism of any kind; and the only assignable cause was walking long distances. Hip-baths, quinin, magnesium citrate, and rest in bed were prescribed. A rigor, together with general restlessness, difficulty, and pain in micturition, was followed by the discharge of about an ounce and a half of pus from the urethra, with relief from the previous symptoms. The patient was directed to take fifteen grains of boric acid thrice daily, but he failed to report again and the further progress of the case could not be followed, although it was learned that he returned to his work.

DR. MASSEY suggested that the abscess may have involved one of the seminal vesicles.

DR. JOHN B. ROBERTS also reported a case of prostatic abscess presenting symptoms of influenza. In this case rupture took place into both urethra and rectum, and there was also an abscess of the scrotum.

Stated Meeting, September 23, 1896.

E. E. MONTGOMERY, M.D., read a paper entitled

TREATMENT OF RETRO-DISPLACEMENT OF THE UTERUS,

in which he summarized his views upon this subject as follows: In the treatment of retro-displacements of the uterus the displacement itself is generally not of so much significance as the accompanying complication, and no procedure that does not take cognizance of the latter will prove a satisfactory method of treatment. The proper treatment for the varying conditions may be briefly outlined as follows: In recent cases, in which the uterus is freely movable, the medicated tampon or pessary is the preferable measure. In many cases the former will be required as a preparation for the latter. In recent cases, in which there exists a plastic exudate, together with adhesions (and pus-tubes can be excluded), massage, supplemented by the medicated tampon, and restoration of the mobility of the uterus, are indicated, followed by the use of the pessary. In chronic cases, in which the uterus is movable, curettement, followed by suture of the round

ligaments in front of the uterus through an anterior colporrhaphy, is the best plan. When the displacement is complicated by disease of an ovary or tube, curettement, followed by abdominal incision, with treatment of the diseased appendage and fixation of the uterus to the abdominal wall, is the course to be pursued. When there exist adhesions, without serious tubal or ovarian disease, curettement and shortening of the utero-sacral ligaments, after separation of the adhesions through the posterior vaginal incision, will be the measures indicated.

DR. G. E. SHOEMAKER said that in the treatment of retroversion of the uterus great care must be exercised to determine whether or not the condition is the cause of the symptoms present. In many cases these are due to secondary displacement of the ovary, to relaxation of the broad ligaments, with resulting venous congestion, and edema, and impaired circulation of uterus and ovaries. Failure to correct these secondary conditions will result in persistence of the symptoms. The pessary is at best but a temporizing expedient, and is without use in the presence of adhesions. It is, however, useful in a small number of comparatively acute cases as a temporary device to support the uterus until involution can take place. To effect permanent relief, both the pessary and such an operation as shortening of the round ligaments are useless when adhesions are present. Under these circumstances an abdominal operation becomes necessary, and the best is ventrofixation of the uterus. The difficulties that have been noted in the sequence of this procedure can be largely obviated by placing the uterine sutures in advance of the line of the tubes instead of behind that line. Vaginal operations are usually not advisable.

DR. J. M. BALDY maintained that retro-displacements attended with suffering are almost always complicated, and complications of any kind contraindicate the use of the pessary. Many cases of retro-displacement are free from all symptoms, and require no gynecologic treatment whatever. The pessary is probably responsible for pelvic suppuration in some cases. In Dr. Baldy's opinion massage of the uterus is only a refinement of masturbation, and without utility, except when a large amount of lymph has been thrown out into the pelvis. For the complications that attend retro-displacements one of two operations is indicated—hysterorrhaphy, or shortening of the round ligaments. Other abdominal operations are not to be recommended, and vaginal operations are dangerous. Dr. Baldy preferred hysterorrhaphy to shortening of the round ligaments. Both have, however, only a limited field of application.

DR. J. M. FISHER pointed out that when a retro-displacement of the uterus is recognized, inquiry should at once be made for the cause. The majority of such displacements are to be traced to the puerperal state, and are attributable to lacerations of the pelvic floor, distention of the bladder, and of the rectum, the protracted use of a binder, and septic processes. When, with a movable uterus, a retro-displacement exists during pregnancy, or when such a displacement occurs shortly after labor during the process of involution, a pessary may prove useful.

DR. W. E. ASHTON divided retro-displacements into acute, chronic, and complicated. In recent and uncomplicated cases the pessary is the only form of treatment available. An uncomplicated case in which relief does not soon follow the use of a pessary becomes a chronic case. If symptoms are absent no treatment is required. Otherwise, surgical intervention becomes necessary. Under these conditions ventrofixation of the uterus, properly performed, is the preferable procedure. In complicated cases the complicating condition must first receive appropriate treatment. When adhesions are present these must first be broken up; when ovaries or tubes are diseased they must first be extirpated. Under these conditions the best treatment is supravaginal hysterectomy.

DR. MASSEY contended that the initial trouble in all cases of retro-displacement is an inflammatory condition of the uterus, and the best treatment for this consists in a stimulation of the metabolic activities of the tissues by means of intrapelvic applications of electricity.

DR. G. G. DAVIS said that the pathology of retro-displacements is to be found in alterations in the pelvic floor, such as attend labor.

DR. W. S. STEWART attributed to the prevailing mode of dress the principal influence in the causation of retro-displacements of the uterus, resulting in depression of the waist, and compression and displacement of the abdominal viscera.

In conclusion, Dr. Montgomery added that the pessary is of especial utility in the relief of recent retro-displacements, *e. g.*, following parturition. The uterus does not rest upon the posterior bar of the pessary. The uterus must be restored to its normal position before the pessary is introduced. The operation of shortening the round ligaments is only available when the uterus is freely movable, and can readily be replaced and maintained in its proper position. If, in performing ventrofixation, union is established between a small portion of the uterus and the anterior abdominal wall, this band will elongate and permit of movement on the part of the uterus, with less danger of complications. In operating, Dr. Montgomery introduces one suture about the center of the fundus in the transverse line, and another just behind this. The operation of shortening the round ligaments is not applicable to all cases of retro-displacement on account of the degenerative changes in the ligaments, when the condition has existed for a long time.

DR. JOHN M. FISHER exhibited a specimen of multiple fibroids of the uterus, removed from a patient fifty-two years old. There had long been present symptoms of pelvic disease, and the patient had passed a considerable period of invalidism. Complicating the uterine condition was a cyst within the folds of the broad ligament on the left side, which, upon superficial observation, resembled the bladder. The uterine appendages on both sides were also diseased. The progress of the case following the operation was satisfactory.

Stated Meeting, October 14, 1896.

F. W. TALLEY, M.D., read a paper entitled

THE PROPER POSITION OF CELIOHYSTEROPEXY IN GYNECOLOGY.

He cited the objections that had been raised to the

operation, and pointed out that the dragging pains that had been observed to follow in some cases could be attributed to drawing the uterus too high in the pelvis. That the operation predisposes to abortion is an objection aimed at the method employed, and not at the operation itself. If the uterus be attached to the abdominal wall by unyielding buried sutures, or by a broad, firm band of adhesion, it will not enlarge uniformly in accordance with the demands of the developing ovum, and the uterine contents may be expelled, though this does not occur often. If, however, the uterus be so attached as to be still capable of a considerable range of movement, this danger will be minimized. That labor is likely to be complicated, and that Cesarean section should have been a necessary resort in a few cases, is again a fault of the method employed. With the uterus lightly supported and free to move, a serious result could not be anticipated. The operation that has yielded Dr. Talley the best results in parous women consists in a small median incision, under septic precautions, separation of the uterus and appendages from adhesions, elevation of the fundus, determination of the point above the pubic symphysis, to which the uterus may be raised without undue tension upon its ligaments and its suture with two stitches. Boiled silkworm-gut is preferred for sutures, the first strand being passed through the entire thickness of the abdominal wall at the point selected, through the fundus of the uterus in a line midway between the two tubal attachments, embracing about half an inch of the uterine tissue, and through the abdominal wall on the opposite side. The second suture is introduced similarly one-quarter of an inch behind the first on the posterior aspect of the fundus. These stitches are tied tightly, and the remaining wound in the abdomen is closed in the usual manner. The stitches in the abdominal wound are removed in eight days, while those holding the uterus are permitted to remain until the sixteenth day. The patient is preferably kept in bed for three weeks. Celiohysteropexy is indicated whenever a uterus that is displaced posteriorly and is adherent cannot be restored to its normal position by non-operative measures, and symptoms of the following kind are present: Disordered and painful menstruation; backache; bearing-down pain; obstinate headache; loss of appetite; difficulty and pain in defecation, and various general reflex nervous symptoms that cannot be relieved by persistent local treatment. For the relief of prolapse of the uturus in parous women celiohysteropexy is an important adjunct to the plastic operations for the narrowing of the vagina.

DR. CHAS. P. NOBLE said that in his own experience he had not observed dragging pains in the sequence of celiohysteropexy, nor in a study of some 800 cases operated on by American surgeons had this symptom been noted. In these cases, and also in some 600 from foreign sources, there was no evidence that the operation predisposed to abortion. The pessary has a useful place in the treatment of retro-displacements in recent and puerperal cases. When operation is required Dr. Noble prefers that of shortening the round ligaments.

DR. MONTGOMERY suggested that the method of operation described would result in too firm or too light union of the uterus with the abdominal wall. In view of the possibility of difficulty during gestation and parturition, it would perhaps be a better plan of procedure to fasten the round ligaments to the anterior surface of the uterus.

DR. JOHN C. DA COSTA said that the patients who complained of pain following the operation were either hysterical or neurasthenic. The introduction of through-and-through silkworm-gut sutures in the abdominal wall, and their retention for sixteen days, will be attended with danger of dystocia.

DR. J. CHESTON MORRIS stated that he had relieved retroflexions almost without exception by means of the intra-uterine stem-pessary. When a stimulating effect is required a galvanic pessary made of zinc and copper will often yield excellent results.

A. O. J. KELLY, M.D., read a paper entitled

ESSENTIAL PAROXYSMAL TACHYCARDIA, WITH THE REPORT OF FOUR CASES.

The opinion was expressed that the seizures are attributable to transitory disturbance of the functional activity of the vagus—most probably of the centers in the medulla. When the heart-beat is less frequent there may be irritation of the sympathetic. In some cases both sets of phenomena are perhaps present. The affection may thus be looked upon as a neurosis, the manifestations of which may be referred to functional failure of the neuron in consequence of nutritional or allied disturbance. The prognosis is uncertain, and the treatment symptomatic. Thus, relief may be afforded by pressure on, or by electric stimulation of, the vagus in the neck, by pressure upon an ovary, by the drinking of cold water or of hot coffee, or by deep inspiration and the retention of the air in the lungs. Of aid are the application of an ice-bag to the chest, the swallowing of cracked ice, and a cold douche upon the chest, abdomen, or neck.

DR. A. A. ESHNER said that in a considerable number of cases of vaso-motor ataxia in which he had examined the urine, he had found red corpuscles in varying numbers. This occurrence may be attributed to the escape of the cells through the capillaries of the kidneys, relaxed as a result of diminished vascular tone.

DR. S. SOLIS-COHEN was unwilling to agree with any nosologic scheme that would sharply separate cases like those reported from all other cases of cardiac and vaso-motor disturbance. When there exists a large group of pathologic phenomena, comprising cases that shade into one another imperceptibly, it would be a philosophic blunder to draw a sharp line at any one point arbitrarily chosen, saying that cases on this side belong to one group, and cases on that side to another. Tachycardia is thus to be looked upon not as a disease but as a symptom. In considering the adaptation of the theory of the motility of the neuron to the explanation of the phenomena of essential tachycardia, the question arises, why is the contact of the arborescent extremities of the neuron interfered with? It may be assumed that the paroxysm is a toxic manifestation, the toxins being many in number and various in character. These interfering with the functions of the

neuron, the other conditions may occur. To go a step further, it may be assumed that a fundamental fault exists in the physical, chemic, or vital constitution of the nervous centers of visceral life, a failure of development that may be congenital, indeed hereditary; or a similarly faulty constitution acquired as the result of various depressing influences, perhaps infectious disease.

DR. WHARTON SINKLER said that the occurrence of tachycardia in cases of neurasthenia is so common that it is natural to associate the conditions productive of the one condition with those that lead up to the other. The theory of the motility of the neuron, while attractive, is not supported upon any firm foundation, and is purely speculative. Essential tachycardia is probably a disorder of nutrition, as in the cases of neurasthenia in which it is present, it disappears with the primary condition as the state of the nutrition improves.

DR. J. P. C. GRIFFITH disapproved of the employment of the qualification "essential," as a cause must exist, although it escapes observation. The condition is thus equally symptomatic with others in which the cause is more obvious. Dr. Griffith referred to the tachycardia of the menopause, which is often observed in conjunction with other disturbance.

DR. J. C. WILSON referred to two cases of essential tachycardia recently under his observation, one in a man who had endured great hardships in consequence of shipwreck, the other in an elderly lady following anxiety attending the illness of a child, and in addition some pecuniary loss. In both occurred long intervals of relief from symptoms, with recurring paroxysms of great suddenness, and usually without immediate obvious cause. Dr. Wilson coincided in the view that even essential tachycardia must be considered symptomatic.

DR. THOS. J. MAYS expressed the conviction that in some cases of tachycardia organic changes in some part of the nervous system are present. He concurred in the view that in many cases the accelerator nerves are concerned, while the vagus or the medulla oblongata is principally involved. Dr. Mays has found paroxysmal tachycardia associated with angina pectoris and with lead-poisoning. Other metallic poisonings, as well as alcoholism and syphilis, may also act as causes. It was thought that the disorder may be allied to epilepsy and asthma. In treatment, no one remedy or plan is successful. Applications of ice to the neck have been useful in some cases. Most are benefited by strychnin, in conjunction with general supporting treatment.

DR. KELLY, in conclusion, maintained that according to the definition given, there are in addition to cases of symptomatic or reflex tachycardia others that may be properly designated "essential." In many the ultimate etiology is toxic in character; in a number the disturbance is nutritional. The best treatment is practically symptomatic.

CHAS. W. BURR, M.D., read a paper on

THE RELATION OF ANEMIA TO CHOREA.

He reported the results of a study of the number of red blood-corpuscles and of the hemoglobin-estimation in thirty-six cases of chorea. The hemoglobin and the corpuscles were found at the theoretic normal in only two cases. In none was there extreme anemia. In the most aggravated case, the hemoglobin-estimation was forty-five per cent., and the number of red corpuscles 3,450,000. The attack of chorea was mild, but a serious cardiac complication existed. In another case, complicated by epilepsy, the hemoglobin-estimation was sixty per cent., and the number of red corpuscles 3,600,000. In one very aggravated uncomplicated case, the hemoglobin-estimation was sixty-five per cent., and the number of red corpuscles 4,800,000, and in another the hemoglobin-estimation was sixty per cent., and the number of corpuscles 3,850,000. These were the most anemic cases. In twenty-four the hemoglobin-estimation reached eighty per cent. or more, and the number of corpuscles 4,000,000 or more. In twenty-nine the hemoglobin-estimation reached seventy-five per cent. or more. The conclusion was expressed that the blood is rarely absolutely normal during an attack of chorea. There is usually a diminution in the hemoglobin-valuation, and a relatively smaller diminution in the number of red corpuscles. The anemia is therefore chlorotic in type. There is no relation between the severity of the attack and the intensity of the anemia. When the anemia is profound there is usually some complication capable of inducing such a condition. The belief was expressed that anemia is not an immediate, direct, exciting cause of chorea, but infrequently even a predisposing cause. In the large majority of cases the condition of the blood is secondary to the chorea. In the rare cases of chorea that seem to result from mycotic infection, the anemia may be of toxic origin.

DR. SINKLER stated that in the larger number of cases of chorea that come under his observation, anemia is not present. A study of the blood in a considerable number showed generally high valuations for corpuscles and hemoglobin.

DR. ALFRED STENGEL related that in his experience anemia is not a frequent complication of chorea. Although many patients are pallid, examination of the blood fails to disclose any considerable degree of depreciation. It is doubtful if there is even a quantitative anemia. Such deficiency as exists may be attributed to the toxic condition secondary to the infection on which chorea may be supposed to depend. In some cases a moderate degree of leucocytosis has been found. Examinations of the blood in dispensary patients are likely to be fallacious, owing to emotional and vaso-motor disturbance.

DR. JAS. TYSON pointed out the entire compatibility of pallor with a normal composition of the blood as manifested in attacks of syncope.

DR. SINKLER raised a question as to the liability of personal error in counting the number of blood-corpuscles and estimating the hemoglobin-valuation.

DR. STENGEL replied that the liability to error diminishes with the skill of the observer. The variations among novices may be very considerable.

DR. BURR, in conclusion, suggested the possibility that many of the cardiac murmurs heard in cases of chorea and attributed to the state of anemia apparently present, may be due to actual disease of the endocardium.

REVIEWS.

A SYSTEM OF SURGERY. In Contributions by Twenty-five English Authors. Edited by FREDERICK TREVES, F.R.C.S., Surgeon to and Lecturer on Surgery at the London Hospital; Examiner in Surgery at the University of Cambridge. Volume II. In one octavo volume of 1120 pages, with two colored plates and 487 illustrations. Lea Brothers & Co., Philadelphia and New York.

WE have here the second and concluding installment of a valuable contribution to surgical literature, the work of men of acknowledged authority as representatives of the profession in Great Britain. This volume is devoted almost entirely to the discussion of the diseases and injuries affecting the various regions of the body.

The opening article is by Mr. Arbuthnot Lane, on the injuries and diseases of muscles and tendons. It is followed by a chapter on the surgery of deformities, by Mr. H. H. Clutton. Mr. Henry Percy Dean contributes two articles, one on injuries of the head, and the other on the diseases affecting that region. Dr. W. H. Bennett discusses first the injuries and then the diseases of the spine; the former paper being supplemented by a brief essay from the pen of Mr. H. W. Page on concussion of the spine, with special reference to that form of traumatic neurosis to which the term "railway spine" has been applied. Next come chapters on the diseases and injuries of the ear and of the nose, by Mr. A. Marmaduke Sheilds; on the injuries and diseases of the neck, by Mr. Bernard Pitts, and on the surgery of the chest, by Mr. A. Pearce Gould. Affections of the mouth, palate, tongue, tonsil, and pharnyx, are discussed by Mr. H. F. Waterhouse, and a separate chapter of ten pages, written by Mr. W. Bruce Clark, is assigned to the troubles which are met with in the esophagus. Next comes an article by the editor, Mr. Treves, on the injuries and diseases of the abdomen. We trust we shall not be regarded as hypercritical, but it seems to us that it would be more accurate to say "of the abdominal organs." Mr. Treves has himself dealt also with the subject of hernia. Dr. Charles B. Ball gives a chapter on diseases of the rectum, and Mr. W. Watson Cheyne follows with one on diseases of the breast. A chapter on the injuries and diseases of the urinary organs, and another on those of the testes, scrotum, and penis, have been contributed by Mr. Henry Morris, and the volume concludes with a discussion of the injuries and diseases of the female genital organs, by Mr. J. Bland Sutton.

In our review of the first volume of this work we referred to the editor's statement in his preface that it was not his intention to dwell upon the details of surgical procedures. As might be expected, this abstinence is more noticed in the portion devoted to regional surgery, and perhaps the scope of the work would have been more correctly indicated had the title been "The Principles of Surgery." The doctrines held by the conservative school of British surgeons are clearly and concisely set forth. One feels that the authors are expressing opinions of their own, and not such as have been manufactured abroad. Had space permitted, we should gladly have entered upon an analysis of some of the views contained in these pregnant chapters.

The mechanical execution of these volumes is highly creditable. The illustrations vary in artistic merit, but they are all adapted for their main purpose in the elucidation of the text.

OBSTETRIC ACCIDENTS, EMERGENCIES AND OPERATIONS. By L. CH. BOISLINIERE, M.A., M.D., LL.D. Late Emeritus Professor of Obstetrics to the St. Louis Medical College, Etc. Philadelphia: W. B. Saunders. Pp. 381.

THE author announces in the preface that this volume is intended "for the use of the practitioner who, when away from home, has not the opportunity of consulting a library, or of calling in a friend in consultation." The matter is newly written, but includes little that has not been repeatedly said in the treatises on midwifery and the manuals of obstetrics, which the author frankly says his book is not intended to replace, and which should be at the working service of every obstetrician at home or abroad. The man who knows only what is herein taught would be an unsafe attendant in the lying-in chamber. The illustrations constitute the best feature of the work, but they are already familiar to readers of "The American Text-Book of Obstetrics," and are often at variance with the text, notably in the chapter on forceps.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 13, 1896, TO OCTOBER 19, 1896.

Captain Wm. H. Gray, Assistant Surgeon, to be Surgeon, with rank of Major, October 10, 1896, vice Gardner, promoted.

Captain Benjamin Munday, Assistant Surgeon, will in addition to his present duties at Fort Wayne, Mich., examine recruits enlisted at Detroit, Mich., and will furnish medical attendance at the recruiting station in that city.

Colonel Francis L. Town, Assistant Surgeon-General, is at his own request, having served over thirty years, retired from active service this date, October 10, 1896.

Captain N. S. Jarvis, Assistant Surgeon, U. S. Army, granted six months leave of absence with permission to go beyond sea.

Captain Jefferson D. Poindexter, Assistant Surgeon, will be relieved from duty at Fort Riley, Kas., and will report in person to the commanding officer, Willets Point, N. Y., for duty at that post.

Captain William P. Kendall, Assistant Surgeon, U. S. Army, is relieved from duty at Fort Sam Houston, Tex., and ordered to Fort Brown, Tex., for duty at that post, to relieve Major Peter J. A. Cleary, Surgeon, U. S. Army.

Major Peter J. A. Cleary, Surgeon, upon being relieved from duty at Fort Brown, Tex., by Captain Kendall, Assistant Surgeon, will report in person to the commanding general, Department of Texas, for duty as Chief Surgeon of that Department.

Major Henry McElderry, Surgeon, is relieved from duty at Fort Robinson, Neb., at expiration of his present leave of absence, and is ordered to Fort Leavenworth, Kas., for duty at that station, to relieve Major Calvin De Witt, Surgeon, U. S. Army.

Major Calvin De Witt, Surgeon, upon being relieved from duty at Fort Leavenworth, Kas., is ordered to Fort Monroe, Va., for duty at that station, to relieve Major Edward B. Moseley, Surgeon, U. S. Army.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, NOVEMBER 14, 1896. NO. 20.

ORIGINAL ARTICLES.

THE ANTITOXIC AND THE ANTISEPTIC METHODS IN THE TREATMENT OF TYPHOID FEVER.[1]

BY MORRIS MANGES, A.M., M.D.,
OF NEW YORK;
ASSISTANT VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL, NEW YORK.

THE theoretical knowledge on which the hydriatic, the antitoxic, the antiseptic, or indeed any treatment of typhoid fever is based to-day is absolutely inadequate. Facts which appeared definitely established only a few years ago, are now rendered doubtful by new discoveries or the application of different methods of research.

It is quite generally accepted that typhoid fever is a disease due to the presence in the system of the typhoid bacillus and its products; but the exact manner in which this microörganism acts, how it enters the system, and how it elaborates its poison are by no means definitely settled. The majority of observers believe that the typhoid bacilli penetrate the mucous membrane of the intestine, usually through some lesion, however slight, and thus reach the lymphatic system; some enter the blood and pass to the spleen and other organs, the intestinal lesions being a direct result of the local infection. Others (among whom we may mention Sanarelli) believe that the bacilli quickly reach the spleen as above stated, and there elaborate toxins which indirectly cause the intestinal lesions.

A great deal of uncertainty has been caused by the relations of the coli bacillus. The differentiation of this germ from the typhoid bacillus was for a long time a matter of great difficulty. (An extended trial, at the Mount Sinai Hospital, of Elsner's method for the rapid differentiation of the typhoid bacillus showed that the procedure is not reliable.) Indeed, there are some observers, the most eminent of whom is Roux, who maintain that the typhoid bacillus is merely a transformation-form of the coli bacillus. The universal presence of the latter in the intestinal tract, and consequently its constant association with the typhoid bacillus, are facts of which the importance has only recently been recognized.

[1] Read before the New York Academy of Medicine, Section on General Medicine, October 20, 1896.

It is possible that the relation of these two germs may be of great significance in the treatment of typhoid fever. Thus, at a recent meeting of the Lyons Medical Society, Rodet showed that a very close relationship exists between the toxins elaborated by these two microörganisms, and that the febrile reactions in animals which have been inoculated with cultures of them are remarkably alike. The serum obtained from these animals has similar qualities in immobilizing and precipitating the microbes with which they have been respectively inoculated. The protective action of the serum of each was not limited to the microbe that had furnished the material with which the animal had been inoculated, although upon that organism it was the more pronounced; so that, for example, the coli bacilli were almost inert in the presence of serum from the sheep that had received the Eberth's bacillus. Neither the coli-bacillus serum nor the Eberth's bacillus serum had any influence on the Loeffler bacillus. Widal[3] has recently published a method for diagnosticating typhoid fever, which also shows the close relation which exists between these two microörganisms. In eighty cases he invariably observed that the serum of patients suffering from typhoid fever, when added to fresh cultures of coli bacilli, agglutinated and precipitated the latter, as above stated. The researches of Pisenti and Biancho-Mariotti[3] also show how close is the relationship between these two microbes.

Sanarelli[4] found that injections of typhoid bacilli under the skin of guinea-pigs did not cause infection; but if, at the same time, he injected sterilized bouillon-cultures of the coli bacilli into the abdominal cavity, the animal became infected.

Chantemesse and Widal,[5] working independently of Sanarelli, reached the same conclusions. Furthermore, these observers show that old cultures of typhoid bacilli, which are practically no longer active, are roused into activity when mixed with cultures of coli bacilli.

A number of observers, among whom we may mention Stern, Sittman, and Bruschettini,[6] have also frequently found staphylococci in the blood of typhoid-fever patients.

Neither is there any agreement as to the exact toxins which are generated by the typhoid bacillus,

as has been clearly shown by Vaughan in the last edition of "Ptomaines and Leucomaines."

Moreover, Dreschfeld[7] believes that the fever during the first eight or ten days is probably due to the direct action of the bacilli or of the toxins; but during the second and third weeks, when the intestines are ulcerated, another factor is probably the absorption of some septic material into the blood, coöperating with the specific poisons.

The next factor, that of immunity, naturally brings us to the consideration of the so-called antitoxin-treatment. Suffice it to say, we must distinguish between the bactericidal and the immunizing powers of the blood-serum. Thus the serum of patients, both during and after typhoid fever, has a marked bactericidal action upon typhoid bacilli and on other microörganisms; but in this respect it is less powerful than that of persons who have never had typhoid fever. Some observers have stated that this difference is due to the using-up of the so-called protective albumoses during the course of the disease. That the blood of these patients is not powerfully bactericidal against Eberth's bacilli is shown by the fact that these organisms grow freely in the blood during the disease, and, experimentally, it has been shown by Stern[8] that if typhoid bacilli be added to the blood of typhoid-fever patients, only a portion of them will be destroyed, while the remainder will proliferate very rapidly.

On the other hand, the blood-serum of many typhoid-fever patients has marked immunizing properties, which are retained even for a very long period after the cessation of the disease. Thus, Stern[9] has found that it was present in six out of eight convalescents from two to twenty-six days after the last day of the fever, and in three out of five patients from one to ten years after the disease, but it was absent in two patients who had survived the disease over ten years.

Experiments show that infected animals can be saved by the injection of typhoid serum, even many hours after they have been infected.

Attempts have also been made to cure typhoid fever by the injection of bacterial products in various ways: (1) Sterilized cultures of typhoid bacilli; (2) similar cultures of other microbes; (3) serum of immunized animals; (4) serum of convalescent typhoid-fever patients. The first extensive trials of this form of therapy were the well-known cases of Fraenkel,[10] who treated fifty-seven cases by injecting sterilized attenuated cultures of typhoid bacilli, which had been grown on beef-tea made from thymus-glands. These glands were chosen because typhoid bacilli grow actively and virulently in this medium, and also because the secretions of these organs cause a marked leucocytosis when injected into the circulation. Fraenkel claimed that the injections produced a distinct reaction, shortened the duration of the disease, and converted the continuous fever into a remittent. The injections were repeated several times during the course of the disease. The mortality was not published. That these results are due to no specific action of the cultures was shown by Rumpf,[11] who treated thirty cases with similar cultures of the *Bacillus pyocyaneus*. Two cases died. Kraus and Buswell[12] also tried this method on twelve patients, of whom two died; the general results were unsatisfactory. Von Jaksch's experience was the same.

Neisser[14] and Hammerschlag[15] employed the serum of convalescent patients, but without obtaining any definite results. The latter used from 40 to 80 c.c. of serum in five cases, but only once did he see a decided result follow the injection, and this was only temporary. Chantemesse and Widal,[16] F. Klemperer and Levy,[17] and Stern[18] used the serum of immunized animals, but the results obtained were poor. As an example cases of Klemperer and Levy may be quoted. They injected 20 c.c. of the serum of immunized dogs for three successive days, in five patients, during the first week. Morning remissions began on the third day after the injections, and apyrexia was complete by the end of the second or third week. In one case there was a slight relapse. They admit that the cases might have been mild.

Beumer and Peiper[19] by inoculating sheep obtained an antitoxic serum, with which they successfully immunized guinea-pigs. The serum is harmless to human beings, and produces a reaction, but has not yet been employed in the actual treatment of the disease.

The only extensive trials which have been made in the United States with Fraenkel's method have been those of Lambert of New York[20] and Henshaw of Boston.[21] The results in Lambert's 28 cases were as follows: in 15 there was more or less improvement; in 12, no results, probably because the treatment was begun too late; 1 died of hemorrhage. Henshaw's cases were 13 in number. Of these, 8 were satisfactory, 4 showed no decided change, 1 died of hemorrhage. On the other hand, Northrup, in so far as he could judge from 11 of Lambert's cases who were patients of his at the Presbyterian Hospital, is emphatic in his condemnation of the method.

Another form of serum-therapy which, however, strictly speaking, does not belong to the above-

mentioned procedures, is that of the so-called artificial-serum treatment, which was first proposed by Dastre in 1889, and subsequently employed by Sahli, Pinard, and Cheron. The idea is "to wash the blood." Animals are infected, are then freely bled, and artificial serum is injected. The latter is given either in one large injection, or in repeated small ones.[22]

The future can alone decide how much will be accomplished with these methods. The number of cases is too small and the procedures employed are too varied to permit the drawing of any inferences. Is it not possible that the close relations existing between the coli and typhoid bacilli and their serums may be practically employed in the solution of this problem?

Next as to the antiseptic method, so-called. It is indeed peculiar that practitioners have eagerly seized upon this idea long before Eberth's discovery, for antiseptic measures were long ago used by Sir William Jenner, Murchison, Niemeyer, Wilks, Liebermeister, Jürgensen, and Ziemssen. Furthermore, Broadbent, Barr, Wood, Shattuck, Yeo, and many others have been most enthusiastic in its praises, and to-day it may safely be said that it is used by most practitioners in some way or another.

The object of the antiseptic treatment is not to kill the microörganisms in the intestines or in the blood, but, if possible, to diminish, even to a slight degree, their activity, or to neutralize the poisons which they have produced. To the objection that it is impossible to act upon bacteria or poisons which are circulating in the blood, we need only point, as has been said, to the influence of quinin, mercury, and salicylic acid in the diseases for which they are the respective specifics.

As already pointed out, the fever in the second and third week is probably partly due to influences which arise from the ulcerated intestinal areas. Furthermore, we must also bear in mind the close relations existing between the typhoid and the coli bacilli. These factors would indicate that therapeutic measures ought to be employed which will act upon these intestinal conditions.

The question which naturally arises is not: Can we disinfect the intestines, but can we lessen, even in some small degree, the specific local inflammation and the bacterial activity? The former may at once be dismissed, for no agent is known which will have any such action. In answer to the second, much interesting work has been done. Thus, it is definitely established that it is impossible to disinfect the intestines. It is also certain that the ordinary drugs used in the antiseptic treatment of typhoid fever are not able to kill microörganisms whose resistance is less than that of the typhoid bacillus. Stern[23] has recently demonstrated this in a most convincing manner. He chose the *Bacillus prodigiosus*, because it is a germ which can safely be administered, its reactions are so characteristic, and, finally, because it can grow in the absence of oxygen at the bodily temperature. The germs were swallowed with food after some of the antiseptic had been taken, and the administration of the latter was continued for some time after. He used salol (4 to 8 grams daily), naphthalin (0.5 gram, ten times daily), camphor (1 to 2.4 grams daily), beta-naphtol (0.5 gram, four to twelve times daily), and calomel (0.3 gram, three times daily). After all of them, numerous living prodigiosi bacilli could be found in the stools. The same results were obtained when the preliminary dose of the antiseptic was omitted.

Stern[24] also attacked this question from a different standpoint, *i. e.*, he counted the number of microörganisms in a definite quantity of feces, before and after the use of various antiseptics. When any lessening was present, it was but trifling. Similar results have been obtained by Fuerbringer[25] and other experimentors. On the other hand, Bouchard,[26] Sucksdorff,[27] and others claim that the diminution was marked. However, experiments of this kind are of little value, as the normal variations in the number of bacteria in the feces are very great, and, besides, we have at present no positive methods for ascertaining whether the virulence of the surviving microorganisms may not have been diminished. Additional experiments were made by Stern[28] to determine whether the feces, after the use of antiseptics—calomel, for example—contained any of the latter in sufficient quantities to prevent or retard the growth of fecal bacteria. In only one experiment was this result observed.

The final argument advanced against the use of intestinal antiseptics is the utter failure of the method in cholera, a disease in which the bacteria remain in the intestinal tract, and is therefore the disease *par excellence* in which intestinal antisepsis ought to be useful.

Surely a strong case has been made against the antiseptic method of treating typhoid fever, so far as conclusions both theoretical and experimental will allow. And yet it is natural to inquire, how is it, then, that the method still survives and is in such general use, even among those who use hydrotherapy in the disease? Is it possible that

so many and such eminent clinicians as those already mentioned have been grossly deceived?

The answer is that, to some degree, both parties may be right, for, as I stated at the beginning, we are not yet in such a position that we can pass a final judgment on any method of treatment of enteric fever. Summarily to dismiss the method, as has been done by so many, is as unjustified as are the sweeping claims of its advocates, based, as they usually are, upon a number of cases which are entirely too small to justify any conclusions. The only treatment of typhoid which can be judged from the statistical standpoint is that of Brand, for its cases are numbered by tens of thousands. It is possible that future methods of research may be devised which will justify the claims of the antiseptic treatment as a specific form of therapy, but at present it must be relegated to the symptomatic method. Here its employment is of value, and from this standpoint we can readily understand why it was so highly prized by our predecessors, and why our own generation is so loath to dispense with it.

From this standpoint, then, let us consider some of the procedures which have been proposed for the so-called antisepsis of the intestines. I shall not even attempt to enumerate the more important of them, for their number is legion. Henshaw[21] naively states that no less than 150 remedies have already been proposed—a sure proof, if any were needed, that none is a specific.

But it is an error to suppose that these procedures are limited to the administration of drugs for the intestines. The care of the diet, the mouth, and of the lower bowel is of primary importance, and is frequently neglected by those who have not had an opportunity of observing a large number of cases of this disease. A foul mouth and a thickly coated and baked tongue will frequently render feeding difficult and may, moreover, predispose to pulmonary complications. In my service at the Mount Sinai Hospital, I have rarely seen the clinical condition of the mouth, of which the text-books tell us so much, except in very severe and septic cases.

The daily administration of enemata of water ought never to be omitted, even when there is diarrhea. When there is tympanites, the addition of turpentine or of quinin is indicated. As has been shown experimentally, quinin causes a downward peristalsis of the intestines.

First of all, let me mention briefly the oldest and one of the most universally used remedies in this disease, namely, calomel. As usually employed, it is given in one large dose or in several smaller doses on successive days in the early part of the disease, before the tenth day. Others employ it during the second or third week—a practice which is not to be recommended. The fall of temperature which usually follows its use is probably due to the evacuation of the bowel. Others claim that part of the calomel is converted into corrosive sublimate, and that part of the beneficial action obtained from calomel is due to this, the splitting-up being due to the sodium chlorid which is present in the intestinal contents. Against the use of calomel, Fuerbringer, Leyden, Stern, and others have protested most vigorously. As already shown, Fuerbringer and Stern have shown experimentally that stools after the use of calomel contain many living organisms which are less resistant than the typhoid bacillus; furthermore, that the number of living germs in such stools is not much reduced. Leyden states that he has frequently seen bloody stools following its use in typhoid fever. Be this as it may, the use of calomel in the early stages of typhoid fever is one of the routine practices with the majority of physicians of the present day, even by some of those who are enthusiastic followers of the hydriatic measures.

As to the claims that the use of calomel can abort typhoid fever, nearly all agree that such claims are unproved, and are based upon either a faulty diagnosis or the nature of the disease.

Corrosive sublimate is another drug which has found much favor and has been used in various ways, either in dilute solutions alone, or in combination with quinin, as recommended by Broadbent,[29] or in enteric pills. My own experience with the drug has been limited to the last method. For some years I have employed enteric pills, consisting of $\frac{1}{100}$ or $\frac{1}{200}$ of a grain of corrosive sublimate enclosed in Waldstein's coating, which consists of shellac and salol.[30] These pills, as I have proven by repeated experiments, do not dissolve in the stomach, unless its reaction is alkaline. It may happen that enteric pills are passed out undissolved in the stools. This is not due to any fault in the manufacture of the pill, but to the fact that, although the intestinal wall itself is alkaline, the part of the intestinal contents in which the pill happens to be is not necessarily alkaline; hence the salol may not be split up. The use of these pills has been followed by an improvement in the general condition of the patient, the stools become less offensive, and the amount of indican in the urine is lessened.

Mineral acids are among the oldest remedies of this group; indeed sulphurous acid was em-

ployed by Wilks in 1871, on a large number of cases (171), with the loss of only one case. It is a striking commentary on the value of statistics that its use never became popular. Much more rational is the employment of hydrochloric acid. As is well known, the secretion of hydrochloric acid is very much lessened in febrile conditions; hence gastric digestion suffers, not alone on account of this deficiency, but also because the presence of acid is necessary for the separation of pepsin and rennet ferments from their respective proenzymes. The antiseptic action of this acid is too well known to require any further comment. For these reasons, the administration of hydrochloric acid ought to be a routine procedure in most cases of typhoid fever. It may be given dilute in water or in milk, or as a lemonade.

And yet, in spite of all these advantages, its usefulness has been questioned by Stern. I shall grant that all his and Hamburger's careful experiments[21] are correct; that hydrochloric acid, especially when combined with albuminates and peptones in the proportions usually occurring in the stomach, does not kill typhoid bacilli; that the *Bacillus prodigiosus*, which is less resistant than Eberth's bacillus, readily passes the gauntlet of the stomach, except in conditions of hyperchlorhydria, and that his experiments corroborate those made by Miller and Macfadyen, yet, clinically all these experiments lose their value.

Salol is another drug of this class, which is very frequently given with a manifold object, for, in addition to any effect which we may perchance obtain in the intestines, it is also a cholagogue and antipyretic of no mean value. Turpentine is still another remedy which owes its popularity not to any antiseptic qualities which it may possess, but to its stimulant and hemostatic properties.

Of the pure antiseptics, I shall only mention chlorin. Its reintroduction into the therapeutics of enteric fever is due to Yeo,[22] who employs it in combination with quinin. The use of chlorin is by no means new, for it was long ago recommended by Murchison. Good results have been obtained by Byers,[23] Wilcox,[24] and others. Wilcox, who obtained excellent results with it in five septic cases, in which many other remedies had been unsuccessfully employed, emphasizes the fact that the use of soluble antiseptics is especially indicated in the middle and late stages, the insoluble ones being employed in the earlier periods. I employed the method in a series of cases in 1894, but saw no special results from its use; moreover, nearly all of the patients complained bitterly of the taste and odor of the mixture.

To enumerate or discuss any more of these so-called antiseptics would be both a tiresome and unprofitable task. Suffice it to say that those which are still in general use owe their popularity to a combination of qualities, rather than to any specific germicidal property.

The persistence in the search for antiseptic remedial measures is the direct consequence, as I have endeavored to show, of the theory that the specific microörganisms must be encountered in the intestines as early and as energetically as possible. I have also endeavored to show that the pathology and biochemistry have by no means been definitely settled as localized in the intestines; and in spite of the recognition of Eberth's bacillus as the specific organism, we are not sure that there may not exist an important relation, be it in combination or be it genetically, with the coli bacillus. In considering these points, is it not possible that all the attempts with the antiseptic treatment *per se* have proven unsuccessful because it itself is an error, and that what we ought to investigate is the question of the specific, rather than the antiseptic treatment; the prophylactic, rather than the topical and curative procedures?

THE EFFECT OF FORMALIN-GELATIN ON SUPPURATION IN WOUNDS; A CLINICAL STUDY.

BY E. M. FOOTE, M.D.,
OF NEW YORK;
ASSISTANT IN SURGERY AT THE VANDERBILT CLINIC.

SOME months ago, Schleich published a report[1] of the results which he had been able to obtain with formalin-gelatin in minor surgical cases, and especially in the presence of suppuration. He treated over two hundred cases in this manner with entire success. The wounds were only mechanically cleansed and then rubbed with a powder of formalin-gelatin, while in the suppurative cases, after incision and escape of the pus, hemorrhage was stilled, and the powder then used as in traumatic wounds. He claimed that an aseptic blood-clot formed in all cases, and that repair took place quickly without the formation of pus. These results were attributed to the action of formalin-vapor, slowly set free over a period of several hours by the digestion of the gelatin by the living tissues of the body.

Formalin is a gas which is readily soluble in water and other substances, but it forms a chemical combination with moist gelatin, and the resulting product is tough, insoluble, and unaffected by acids or alkalies. In a similar manner tannic acid acts upon the untanned hide to form leather. Sheets of moist gelatin after exposure to formalin-vapor are dried and ground to a coarse powder.

Wishing to verify Schleich's claims, I have tested the action of formalin-gelatin in a number of cases at the Vanderbilt Clinic. All of those in which the powder was employed were suppurative ones, as it seemed reasonable to suppose that if it could stop infection already begun, it could prevent it. Beginning with the simplest forms of suppuration, as the method of treatment proved satisfactory, it was gradually extended to the severer cases. My method of using the powder was as follows: The skin was cleansed with soap and water, turpentine, ether, and bichlorid; cocain was injected; a free incision made, and pus and sloughing-tissue curetted away. Hemorrhage was stilled (when time permitted) by pressure with dry gauze, after which the wound was filled with the formalin-powder, and a dry dressing applied. The wounds were dressed daily at first for purposes of observation, though in most instances this was unnecessary. No drains were used, as a drain would defeat the object of the treatment, *viz.*, immediate union.

In all, forty-five cases were treated. Nine of these were either not seen again or were seen only once, and they are therefore excluded. Not one of them, as far as known, developed any unfavorable symptoms. Of the remaining thirty-six cases, three were complete failures. One of them was a suppurating wound involving a joint of the little finger. As it did not appear at the time of operation that the joint was affected, the treatment was insufficient, in that the formalin was not brought in contact with the whole infected area. The following is a report of the case:

R. M., aged thirty years, male, three days before received a cut on back of right fifth digit with a chisel. Infected wound and moderate cellulitis over the second phalangeal joint followed. Wound was enlarged and curetted. Joint apparently was not affected. Formalin-gelatin and dry dressing were employed. First day: Brownish pus was found under a dried blood-scab; finger slightly swollen, and axillary gland tender. Pus was wiped away and dry dressing reapplied. Second day: Wound was found to be suppurating, but axillary tenderness had disappeared. The part was cleansed with peroxid of hydrogen, and dry dressing continued. Third day: Suppuration persisted and joint-crepitus was demonstrable.

In two other cases where suppuration was not stopped by the formalin, no explanation of the failure was evident. The cases were these:

F. T., aged twenty-eight years, male. For one week had suffered from an abscess of finger which broke the day before entrance. Cellulitis of the middle phalanx of right third digit, and a suppurating subcutaneous sinus were evident, but neither bone nor tendon was affected.

Incision, curetting, formalin-gelatin, dry dressing, was the treatment given. First day: Small amount of pus and slough were found, and dry dressing was continued. Third day: More pus was seen and a wet dressing was substituted.

M. S., aged thirty-six years, female. Four days before, an abscess developed at the base of fourth right digit, palmar surface. Cellulitis was moderate. The part was incised, curetted, and a dry dressing with formalin-gelatin applied. First day: Cellulitis had disappeared. Small amount of greenish pus was present. Bichlorid-dressing and gauze were used. Second day: Considerable green pus being present, a new curetting, followed by formalin-gelatin and dry dressing, was tried. Third day: Suppuration was not controlled and a wet dressing was resorted to.

In one other case—the only one of suppurative bursitis treated—the abscess-cavity was so large and the cellulitis so marked, that it seemed like taking a risk to dress it without a drain; but from the result in subsequent cases, I am confident that this was a mistaken precaution.

J. McC., aged thirty-two years, female. For

[1] Schleich, *Therap. Monatshefte*, February, 1896.

twelve days a suppurative prepatellar bursitis had been present. Joint was not involved. By a vertical incision six ounces of pus were evacuated. The cavity extended about three times further toward the inner than the outer side. After curetting, the formalin-gelatin and dry dressing were applied, with a gauze-drain in the larger cavity. First day: Non-drained cavity had collapsed and its walls were adherent; some suppuration occurred from the drained side. Cellulitis was nearly gone. Wet dressing was then applied.

There remain then thirty-two cases which for purposes of study may be divided into indolent suppuration with little cellulitis, acute suppuration with cellulitis, and suppuration which extended to a tendon-sheath (felon) with cellulitis.

In the first class were five cases. No one of these abscesses had a duration of more than three weeks, and there was no suspicion of tuberculosis in any case. They were simply instances which are common enough where the virulence of the suppurative process has somewhat spent itself.

The success of the formalin in this class of cases was very striking. The transformation in two days of an abscess lifting half of the breast up from the chest-wall into two short wounds in the skin is most satisfactory. But it must be admitted that cases of this sort are the easiest to heal, and that indolent subcutaneous abscesses in children will sometimes collapse and heal after an incision is made to evacuate the pus. Four histories from this first class are given.

K. K., aged one and a half years, female. For three weeks an abscess in the neck had existed. Its character was sluggish, and there was no cellulitis. An incision and curetting were followed by the formalin-gelatin and dry dressing. Sixth day: Dressings had been constantly removed by the mother, but no suppuration was discovered, and the incisions were simply skin-wounds.

T. P., aged twenty-five years, female. She had one child, four months old, which was nursed on the left breast on account of small right nipple. Right breast had been sore one week and was fluctuating, but there was no cellulitis. Two one-inch radial incisions to inner and lower sides of right nipple opened into a pus-cavity containing about four ounces of old pus. Irrigation with bichlorid of mercury 1–5000, formalin-gelatin, and dry dressing without drainage comprised the treatment. First day: Upper wound was found to be dry, while from lower wound there was present a small sanguino-purulent discharge. There was no redness. Second day: Not a dram of discharge was apparent. Fourth day: Breast had healed solid to the chest; abscess-cavity was completely obliterated. There was no discharge, but the skin-incisions were indolent. Sixth day: Skin-cuts were granulating.

H. T., aged twenty-six years, male. For one week has had infected wound in palm of hand, making a small, indolent, subcutaneous abscess. Incision and curetting, with formalin-gelatin, and dry dressing formed the treatment. First day: Mouth of cavity was closed by dried blood, with pus and necrotic material underneath. The scab was wiped off, and dry dressing reapplied. Third day: There was no redness nor discharge. Cavity had collapsed. Fourth day: A dry superficial scab was all that remained.

H. McN., aged twenty-five years, male. Has had immense boil on the back of his neck for three weeks. A minute sinus discharged very little pus, and surrounding cellulitis was slight.

After a vertical incision, the old pus and sloughs were curetted out from under the skin which was in good condition. Formalin-gelatin and dry dressing, without drainage, were employed.

Second day: Cavity was nearly obliterated.

Fourth day: Wound was simply a granulating line one-quarter inch wide.

The second class, in which suppuration was active and cellulitis progressing, includes the bulk of the cases, *viz.*, twenty-four. Usually the cause of suppuration was a poisoned wound, and, naturally, most of these were of the fingers. A number of histories are given, though it is impossible to convey an accurate impression of the progress of the cases by such brief notes.

W. T., female, aged forty years. Three weeks before she had scratched the head of a pimple on the back of the neck. Boil was about 1½ inches in diameter, involving the skin and subcutaneous tissues. The surrounding area of acute inflammation was about three-quarters of an inch wide. The treatment consisted of incision, curetting, formalin-gelatin, and dry dressing.

First day: There was a dark-red, jelly-like filling in the wound, but no pus; dry dressing reapplied.

Second day: Jelly-like mass was gone. Wound was gaping, but no pus was found. Dry dressing was again employed.

Ninth day: There was no pus, and wound was nearly covered with epithelium.

P. W., aged forty-two years, male, presented a suppuration following scratch by tin received four days before. Last two phalanges of the fourth right digit were inflamed, and subcutaneous pus was evident. Incision, curetting, formalin-gelatin, and dry dressing comprised the treatment.

Second day: Swelling had subsided, and a soft slough came away. Dry dressing was reapplied.

Fourth day: Wound was doing well. Dry dressing again applied.

Eighth day: Superficial granulation only remained.

J. B., aged twenty-four years, male. Had an abscess of five days' duration in the web of the left thumb. Localized cellulitis was present.

The usual method of incision, curetting, formalin-gelatin, and dry dressing was employed.

First day: Cellulitis and pus had disappeared. Dry dressing was reapplied.

Second day: Wound was moist, but there was no pus. Again applied the dry dressing.

Fourth day: Wound was only one-half inch deep and granulating.

H. K., aged twenty-three years, male. Five days before had scratched his wrist. For two days it had been swollen, and an abscess had developed over the head of the left radius. Incision, curetting, formalin-gelatin, and dry dressing were employed.

First day: Cellulitis was gone, but much brownish pus was found under the formalin-crust. Slight curetting was done and more formalin-gelatin applied.

Third day: Wound was much smaller and granulating.

M. K., aged thirty years, female. For four days her right fourth digit had been painful and swollen. Foci were discovered on both sides of the last joint, that on the outer side fluctuating. Local cellulitis was present. Pus was liberated by incision and curetting. Formalin-gelatin and dry dressing were used.

First day: Swelling and pain have persisted, and inner focus was more prominent. Pus was seen in the wound. A second incision was made on inner aspect of finger. Both sides were curetted, and formalin-gelatin and dry dressing were applied.

Second day: Both cuts were moist, but cellulitis was gone. Dry dressing.

Fourth day: First cut had entirely dried up. The second presented a small cutaneous slough.

Fifth day: Second cut had scabbed over, with a drop of pus under the scab.

Seventh day: Second cut was a small superficial granulation.

As instances illustrative of the third group of cases (suppuration about tendons), the following cases are submitted. The action of the formalin was substantially the same as in the cases of the second class:

J. S., aged twenty-five years, male, for a week had suffered from an inflammation on the palm of right second digit of the first phalanx. Incision; curetting, formalin-gelatin, dry dressing was the treatment. First day: Wound was moist, but there was no pus. Third day: Cellulitis had gone, and recovery was rapid.

J. McC., aged thirty-nine years, male, had been sick several weeks. He had several points of suppuration in neck and hands. The worst was in palm of left hand, where the pus extended down to the flexor-tendons of the second digit. A three-inch incision, curetting, formalin-gelatin, and dry dressing were employed. First day: No pus was found. Central portion of wound contained some necrotic tissue, blood, and moist gelatin. The ends of the wound were already adherent. Cellulitis had diminished. Third day: Cellulitis had not increased. A small amount of pus and much slough were seen in the central part of the wound, and a wet dressing was applied.

CONCLUSIONS.

Unsatisfactory as these brief descriptions are, it must be plain, even from their perusal, that the formalin has some antiseptic action. That was evident enough to one seeing the cases. But it fell far short of the point where one could say that it rendered a suppurating wound sterile. It seemed rather to control the infection for two days; and if the character of the wound was such that this respite was enough to insure its closure, the result was perfect. If not, then whatever gain was made in the first two or three days was maintained, and the wound went on with its customary granulating from that point. This, however, is a distinct advance over the usual treatment. At the end of the second or third day, instead of having a wound distended to its full size by the gauze-packing put in at the operation, one finds, on removing the dressing, a wound perhaps united altogether below the skin—at the worst half united; so that the time, until complete cicatrization has taken place, must be reduced by several days.

A second point in favor of this treatment with formalin-gelatin is that it does away with the necessity for drainage. If the abscess-cavity is large, and there is purulent or serous fluid to escape, it finds its way out readily enough by the side of the mass of gelatin, while the grains of the latter, softened by the fluid, form in themselves an excellent capillary drainage. It was only in one or two cases, in which the abscess was small and superficial and the incision a very short one, that a dried scab prevented discharge.

This brought up the question whether some other powder would not answer as well as formalin. To test this I selected acetanilid and used it in a half-dozen cases, as I had used formalin. It does not readily mix with water, and so it was more unsatisfactory to rub into a wound; but the patients told me that there was no pain after the dressing was put on, whereas there is more or less pain with formalin for four or six hours. The wounds looked so well on the second, and sometimes on the third day, that I had almost concluded that formalin-gelatin acted merely mechanically; but they suppurated, with scarcely an exception, in the course of a few days.

In no case treated did I succeed in getting primary union of the skin. It seems impossible that

Schleich obtained an immediate union of the skin-edges, as, unless they are stitched together, they invariably retract a little. The ideal treatment of an abscess would be to sew it up again, but that is not possible until a more perfect antiseptic is obtained than formalin-gelatin proved in my hands. None the less, it seems to mark a distinct advance in the treatment of suppuration, giving the most perfect results in those cases where the cellulitis is moderate and the pus abundant.

SERUM-THERAPY AND PROTECTIVE INOCULATION.[1]

BY JOHN RUHRÄH, M.D.,
OF BALTIMORE, MD.;
RESIDENT PHYSICIAN, BALTIMORE CITY HOSPITAL; DEMONSTRATOR OF BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

PLINY, in speaking of Mithridates, who was famed for his knowledge of poisons and their antidotes, says that he used the blood of the ducks of Pontus to mix with his antidotes to make them more potent. This he did because he had noticed that the ducks fed upon poisonous substances and remained unharmed. It would seem that Mithridates foreshadowed the modern discoveries in serum-therapy and protective inoculations.

The first important announcement in serum-therapy was made by Babes and Lepp, of the Pasteur Institute, in July, 1889.[2] They reported that the blood of dogs immunized against rabies, when injected into susceptible animals, conferred a certain amount of immunity upon them. The following year both Fraenkel and Behring produced immunity from diphtheria in guinea-pigs.

Diphtheria.—In diphtheria we have an ideal disease in which to use an antitoxic remedy. In the human being, the specific organism grows in a localized area, the absorption by the blood and lymphatics of the toxin produced by the organism causing the constitutional symptoms. The disease is self-limited and the defense on the part of the individual lies in the formation of an antitoxic principle in the blood, that acts directly on the toxin, neutralizing it. Clear it is, then, that if we can introduce into the body, early in the disease, a sufficient quantity of the antitoxin to counteract the effect of the toxin already formed, we have an ideal remedy.

The discovery of the bacillus of diphtheria by Löffler was followed closely by the discovery of its toxin by Roux and Yersin of the Pasteur Institute. Brieger and Fraenkel in 1891 confirmed these discoveries. They found that cultures of the organism grown for some time were more virulent than fresh cultures, or, in other words, smaller quantities of the old cultures produced the same effect as larger quantities of those of more recent date. The toxin, according to Brieger and Fraenkel, is a toxalbumin, and they base their opinion on the following facts :

It is soluble in water and insoluble in alcohol; it is destroyed by a temperature of 60° C., and it will not pass through a dialyzing membrane. Park and Williams in their recent article on the diphtheria-toxin, in the first number of the *Journal of Experimental Medicine*, brought out the fact that the production of the toxin depends upon the reaction of the medium in which the organism is grown. According to them, it is formed best in a neutral medium to which 7 c. c. of a normal soda-solution has been added. The toxin is generally formed in this in from three to seven days.

The production of immunity from diphtheria was first accomplished in 1890 by Fraenkel, and independently in the same year by Behring. Fraenkel injected 10 c. c. of a culture heated to 70° C. for an hour into the abdomen of guinea-pigs. After about ten days' time a transient immunity was observed. If it took ten days' time to produce an immunity, plainly there was but little hope of applying the remedy therapeutically. But while this fact was being discussed by the various medical authorities, Behring and Kitasato announced in their famous article which appeared in the *Deutsche Medicinische Wochenschrift* for December, 1890, their discovery in regard to immunity. This immunity was produced by transfusing blood-serum from an immunized animal into one on which immunity was to be conferred. Behring and Wernicke first produced immunity by injections of cultures attenuated by the use of ter-chlorid of iodin. Aronson, too, deserves great credit for his researches, both in producing immunity and in his practical application of it in the treatment of children.

The first application of the diphtheria-antitoxin to the human animal was made in Von Bergmann's clinic in Berlin during the year 1891, and in the following year by Henoch of Berlin and Heubner of Leipsic. These experiments were only partially successful owing to the insufficient strength of the serum. Stronger and stronger serums were produced and many reports were published, but the subject remained confined to narrow limits. In September, 1894, however, it was made a theme of general discussion and investigation by the

[1] Prize-essay for 1896 of the Alumni Association of the College of Physicians and Surgeons, Baltimore.

[2] I am indebted to Sternberg's book on "Immunity and Serum-Therapy" for many of the statistics contained in this paper, notably in connection with minor reports on diseases of animals and yellow fever.

memorable address of Roux before the International Congress of Hygiene and Demography, held at Budapest.

The antitoxin possesses no bactericidal properties and has no effect on the specific organism itself. It acts directly on the toxin, a definite quantity of antitoxin being required to neutralize a given quantity of the toxin.

For scientific confirmation of the value of the treatment it is only necessary to refer to the analysis of more than 7000 cases by Welch. This analysis shows that the fatality in 7166 cases of diphtheria treated with antitoxin was 17.3 per cent. The reporters of these 5000 cases also reported their previous or simultaneous fatality in the treatment of the disease without the use of the antitoxin. Basing a calculation on their lowest figure, it was found that there would have been a fatality of 42.1 per cent. in the 5000 cases, had the antitoxin not been used. There was, therefore, an apparent reduction in case-mortality of 55.8 per cent. by the use of antitoxin.

The effect of antitoxin on children who have diphtheria is usually very marked, a fall in the temperature and a marked improvement of the general condition being observed. The local symptoms subside much more rapidly than under other methods of treatment. No bad effects follow the administration, the only untoward symptoms being an occasional urticaria.

Tetanus.—Closely associated with the discovery of the new treatment of diphtheria is the discovery of the antitoxin of tetanus.

The specific organism is found at the seat of inoculation in comparatively few numbers, but it forms a poison that is absorbed by the tissues, causing the well-known symptoms of the disease. This toxin is now regarded as a toxalbumin. Brieger was the first to separate it. From bouillon-cultures he obtained a substance which he called tetanin. By further researches, together with Fraenkel, Kitasato, and Cohn, he separated the toxalbumin by precipitating it with ammonium sulphate and thoroughly washing it in water in a dialyzer.

Kitasato, in 1891, succeeded in producing immunity from tetanus in rabbits by inoculating them with the filtrate of tetanus-culture, and afterward with terchlorid of iodin. Blood drawn from these animals is said to destroy the power of the toxin when mixed with it. Behring, continuing his researches, produced immunity in horses by means of a bouillon-culture, to which terchlorid of iodin had been added. He used a culture of which seventy-five hundredths c. c. would kill a rabbit in from three to four days. Carbolic acid sufficient to make a five-tenth-per-cent. solution was added to preserve the culture, and then 10 c. c. of this mixed with twenty-five hundredths per cent. of terchlorid of iodin was injected. At the end of eight days, the horse was given another injection, this time of 20 c. c. Increasing the dose of the culture and decreasing the amount of terchlorid of iodin, the animal was rendered immune, about 200 c. c. of the above-described mixture being necessary to produce the desired effect.

The blood of horses so immunized is very antitetanic ; that is, its immunizing power for other animals is very great. It varies from 1–100,000 to 1–200,000 ; in other words, a man weighing 60 kilograms would require 60 c. c. given in about two days, to produce immunity. After infection has taken place, the quantity of serum necessary to produce any effect must be at least one thousand times as great as that required to cause immunity. Naturally, one could not inject such a large quantity into a human being, nor could the body absorb and dispose of it. The next step in the production of an antitoxin of greater strength was the work of Brieger, Kitasato, and Wasserman. The tetanus-bacillus, grown in thymus-cultures, does not form spores, and is therefore not so poisonous. These cultures were used to immunize goats, and from the milk of these goats there was separated an antitoxin very much more powerful than that formerly produced.

Tizzoni and Cattani made the next advance when they found that they could precipitate the antitoxin from the blood-serum by means of alcohol and so obtain it in a dry form. The dose of this dry antitoxin is from 40 to 50 centigrams. The first application of the remedy to the human being was in a case of Schwartz of Padua. The solid antitoxin was dissolved in water and injected under the skin, 60 centigrams being given in three days. The treatment was started on the ninth day, when the case was regarded as hopeless, but the patient recovered.

According to Sternberg, the dried tetanus-antitoxin has been used successfully in eleven cases. Where rabbit-serum was used in its preparation the cases did not do so well. Maragliano stated before the Italian Congress in 1895 that thirty cases had been treated, and that only thirteen recovered. Vaillard of the French Academy of Sciences takes the following view of the subject: The remedy is powerless to cure fully developed cases of tetanus, either in men or in animals, or the rapid, acute cases, or those in which intense

nervous symptoms have developed, showing that intoxication has taken place. However, he recognizes its value in cases of slow development and where intoxication is gradual. The immunizing power of the remedy may be of considerable practical value, even though the cure of the disease is uncertain. It confers immunity for from two to six weeks, according to the dosage. The antitoxic action is less if it be introduced with the muscle, as the antitoxin seems to cause phagocytosis as well as to act chemically, and phagocytosis is not so active in muscular as in other tissue.

Streptococcus-infection. Of great interest to the surgeon and obstetrician are the researches upon the application of serum-therapy to streptococcus-infection. The *Streptococcus pyogenes* is the etiological factor in puerperal septicemia, in various forms of septic intoxications, and in septicemia from abscesses of streptococcic origin. It is also of importance as occurring in the mixed infection-cases of diphtheria, where it coexists with the Klebs-Löffler bacillus.

Among the earlier investigations in this direction may be mentioned those of Emmerich and De Mattei, in 1886–87. They found that the streptococci injected into rabbits having anthrax, arrested the progress of the disease. Subsequently, they showed that blood-serum from animals with streptococcus-infection would, when given shortly after inoculation, prevent the progress of the disease.

The practical application of serum-therapy to streptococcus-infection, however, was made by Marmorek of the Pasteur Institute. Roger and Charin, however, claim to have been working at the subject for some years.

Marmorek, early in 1895, reported to the Biological Society of France the result of his experiments as regards the curative action of the serum in animals, and in the annals of the Pasteur Institute for 1895 he described his methods and reported his cases. The *Streptococcus pyogenes* loses its virulence rapidly when grown on artificial media; this difficulty was partially overcome by using a mixture of two-per-cent. human blood-serum in one-per-cent. peptone-bouillon, and less satisfactorily by substituting ascitic fluid, using one part fluid and two parts bouillon.

The streptococcus was first obtained from a case of sore throat. By intravenous injection into rabbits, using the blood of the dead rabbits for the succeeding injections, Marmorek succeeded in producing cultures of such virulence that one-billionth of a cubic centimeter, even if diluted, would kill a rabbit. This culture was then injected into larger animals, such as asses, horses, and sheep, the injections being at first very small, 1 c. c. as a primary dose causing very marked illness. The injections were given at rather long intervals. No matter how virulent the culture, at least six months' time is needed in order to obtain an active serum. Four weeks are then allowed to elapse so that the fever may subside. At the end of that time, the animal is bled, and the serum is obtained by the usual procedure. This method differs from those of Behring and Roux in obtaining diphtheritic serum, virulent cultures being used instead of toxins. The sterilized filtered cultures possess but little toxic power.

Horses immunized against diphtheria stand the inoculations much better than any others, and the fact suggested to Marmorek the possibility of producing antitoxins for mixed infections. The preventive power of the antistreptococcic serum prepared in this manner is very great as regards animals. A rabbit weighing 1500 grams, when given one-fifth c. c. of the serum, may be injected with ten times the fatal dose of a streptococcic culture and still remain in good health. Notwithstanding the startling results obtained by the use of the serum in animals, Marmorek has not drawn any hasty conclusions as regards its application to man. In many isolated cases it has proved an excellent remedy, and in erysipelas the death-rate of 3.87 per cent., in place of the usual five per cent., in 413 cases is very noteworthy.

The serum is given in doses of from 10 to 20 c. c., according to the virulence of the particular case. Chrobak of Vienna, while not expressing an opinion on its curative properties, regards it as harmless, and in his case, so far, as very efficient. Chantemesse of Paris gives the following interesting statistics in his service at the Erysipelas Hospital: "Under ordinary treatment there was a mortality of 3.79 per cent. in 554 cases. Using Marmorek's serum of moderate strength, possessing a preventive power of 1–7000, there was a mortality of 1.68 per cent. The supply of strong serum ran out, and during several months a weak serum of 1–2000 preventive power was used. During this time in 107 cases there was a mortality of 6.54 per cent. When the strong serum was again obtainable, a very strong one, having a preventive power of 1–30,000, was used in 97 cases, with a mortality of 1.03 per cent.

"Taken altogether there were 501 cases treated, with an average mortality of 2.59 per cent. This, as compared with 3.79 per cent. mortality under ordinary treatment, is very encouraging,

especially when one takes into consideration the fact that the mortality was greatly raised by the forced use of a weak serum."

Quite a number of cases have been reported in which Marmorek's serum, and that of Roger and Charrin, have been used in puerperal septicemia. The clinical picture in favorable results was about as follows: The cases injected were usually those in which quinin and intra-uterine douches had proved of no avail. After the first injection there was a fall in temperature, and a great improvement in the general condition of the patient. The convalescence had been of but two weeks' duration, and attended by no discomfort. The treatment had also been used in post-operative peritonitis with considerable success. The untoward symptoms caused by the serum are occasional attacks of erythema, and sometimes slight pains in the joints and muscles. In the use of Marmorek's serum, no bad effects were seen unless the serum had been taken without allowing sufficient time to elapse between the injections, when urticaria and local swelling at the seat of inoculation occurred. There are no reports on its use in septicemia and pyemia.

Tuberculosis.—Unlike diphtheria and tetanus, which are ideal diseases for the application of serum-therapy, tuberculosis presents no favorable points, not being a self-limited disease, but going on from bad to worse.

Science took a great step forward when Koch, in 1884, discovered the bacillus of tuberculosis, and his subsequent experiments with tuberculin are of great scientific interest, if not of very much practical value.

The lesions caused by the tubercle bacillus are due to the toxin of the organism, which is to be regarded as a toxalbumin. It is formed in the body and also in cultures grown on artificial media. It is soluble in glycerin, and insoluble in alcohol, and can be separated from the cultures by comparatively easy means. The tuberculin of Koch is a glycerin-extract of this toxalbumin, obtained by growing the bacilli in a five-per-cent. glycerin beef-extract. This is put in flasks with a flat bottom, such as the Erlenmeyer flask, and when inoculated from glycerin-agar or blood-serum cultures, forms a white film over the surface. In about six weeks' time, development ceases and it falls to the bottom. The beef-extract is then evaporated to one-tenth its volume and it is the resulting product that Koch and so many of his followers used in their experiments a few years ago. By treating the extract with alcohol, a precipitate is obtained that has all the toxic properties of the original culture. The tuberculocidin of Klebs is a very much purified precipitate, made by washing the extract in chloroform and redissolving it in carbolic-acid glycerin.

The tuberculin was injected in increasing doses beginning with one-tenth of a milligram. Results were, as a whole, unsatisfactory. Cases of skin-lesions, where the bacilli were few and not very active, were greatly benefited, and some dermatologists still use this treatment in lupus and cutaneous tuberculosis. In animals, such as guinea-pigs, a certain amount of tolerance to inoculations with tuberculous matter can be obtained by injections of tuberculin.

This agent has another use; that of confirming the diagnosis of tuberculosis. It is used in the case of cattle, from one-tenth to five-tenths of a gram of tuberculin, diluted with ten times the quantity of a five-per-cent. carbolic-acid solution, being injected into the shoulder of the animal. If it be tuberculous, a pyrexia of varying intensity will follow. The rise of .5° C. to 1° C. is regarded by different observers as pathognomonic evidence of the presence of the disease. The pyrexia may go higher in severe cases. If the animal is non-tuberculous the reaction will be very slight.

Tizzoni and Centanni were the pioneers in the application of serum-therapy to tuberculosis. They found that the blood of guinea-pigs, immunized against tuberculosis, contains an antitoxin that can be used in the treatment of guinea-pigs suffering from the disease. Richet and Hericourt in 1889, by using blood-serum, were able to retard the progress of tuberculosis in these animals. They claim also to have used with success the blood-serum of an immunized dog in treating tuberculosis in a man, and, subsequently, in a woman.

Bernheim in 1894 obtained some partially satisfactory results by immunizing animals with cultures sterilized at 60° C. for one hour and a half, and then filtered. The blood-serum from these animals was used in doses of from 1 to 3 c. c. Paquin in 1895, by making use of a serum from immunized horses, also obtained results which caused him to think that the serum is a valuable remedy in treatment, rather than a specific. Brivet of Marseilles reported to the Biological Society of France that in 1894 he immunized goats by means of tuberculin. The blood-serum of these goats, in doses of from 2 to 4 c. c., was used in eight cases; three slow, apyretic cases did well, and two cases in the second stage improved; in the later stages the agent proved inefficient or had a detrimental effect. Broca, using the blood-serum of immunized dogs, obtained favorable re-

sults in skin-lesions. Maffuci and De Vesty recently reported the results of the use of blood-serum of sheep, immunized by the injection of dead tubercle bacilli, in the case of experimental tuberculosis of guinea-pigs, and say that it exerted neither a prophylactic nor a curative effect, but merely retarded the morbid process.

By far the most interesting and successful report is that of Maragliano of Genoa before the British Medical Association in July, 1895. He claimed that the experiments of Richet and Hericourt, of Babes and of Paquin, were made with ovian or human tuberculosis, and were not at all encouraging. The method by which he has been experimenting, during the past three years, consists of obtaining toxic substances, that will kill a guinea-pig in two or three days, from virulent cultures of bacilli from the human being. With these he immunized animals naturally refractory to tuberculosis, such as asses, dogs and horses. He said that under the use of his serum the physiological changes taking place in tuberculous subjects are a slower pulse, higher arterial tension, and an increase in leucocytes, and red blood-corpuscles, together with improved appetite and nutrition, and considerable gain in weight. The serum causes no more pyrexia than the serum from healthy animals, unless administered in large quantities.

Leprosy.—Closely allied to the tubercle bacillus, in form and character, is the bacillus of leprosy, the discovery of Hansen.

On November 22, 1895, Carrasquilla reported to the National Academy of Medicine of Colombia at Bogota a series of cases of leprosy treated with antileprous serum. Fifteen cases of the anesthetic type, and several of the tubercular variety, were treated with a remarkable degree of success. Unfortunately, Carrasquilla did not mention the method he uses in preparing the serum, but a note in the *Journal of the American Medical Association* says that it was made by introducing leprous tissue into animals, and subsequently preparing the blood-serum according to the usual method. The results of the treatment by this method are summed up by Medina, who furnished the reports of the cases as follows:

The sensation is restored more or less rapidly according to the extent and gravity of the lesions of the peripheral nervous system. The discolored patches lose their abnormal color without disappearing entirely. Edemata subside rapidly in some cases, slowly in others. The skin shrinks and resumes its physiological condition after absorption of the edemata. Tubercles shrink, break down, and disappear by absorption, desquamation, or suppuration, leaving traces of their existence at the affected spots. Ulcers, after having presented copious purulent secretion, rapidly clean off, and are covered with healthy skin; scars from former suppurating lepromata fade and tend to assume the same level as the surrounding skin. Ulcerating mucous membranes form a cicatrix, fade like the skin, and recover sensibility; while tubercles break down. The face loses its leonine appearance. Lastly, the patient recovers his appetite and ability to sleep, and the mental state improves. Carrasquilla further stated that at a future date he would describe his methods, and show how the various ill effects, arising during treatment, may be effectually prevented.

I am indebted to Dr. Alvarez, who has been in correspondence with the Colombians, for further information upon this subject. He tells me that the serum has not proved as successful as it at first promised to be, and that many cases have relapsed, one patient having died from the disease.

Leprosy is not well adapted to the application of serum-therapy. The disease is one which is not self-limited, and this is one of the principal points to be considered.

(To be continued.)

CLINICAL MEMORANDA.

AMENORRHEA DUE TO COMPLETE OCCLUSION OF OS UTERI FOLLOWING LABOR.[1]

BY L. GRANT BALDWIN, M.D.,
OF BROOKLYN, N. Y.;
GYNECOLOGIST TO ST. PETER'S HOSPITAL.

COMPLETE occlusion of the internal os due to injuries received at childbirth or from instrumental interference is not common. I have seen two cases. When it does occur hematometra, pyometra, or physometra, are the expected results. In the case reported a simple amenorrhea followed.

Mrs. X. consulted me February 19, 1894, and at that time gave the following history: She was thirty-three years old, married seven years, the mother of one child at full term, December 16, 1891, and one abortion at two weeks about one year earlier. The child was born dead, supposed to be due to a very hot bath taken five days before labor commenced. Labor was normal so far as she knew, she was in bed thirteen days, and had some fever (101°), for which the nurse gave intra-uterine injections. The milk appeared in the breasts and was dried without any mastitis; the flow lasted three weeks, otherwise the puerperium was uneventful.

Six weeks later the patient had crampy abdominal pains

[1] Reported before the Kings County Medical Association June 9, 1896.

lasting for three days; these recurred from fourteen to twenty-one days for several times, and then every twenty-five days up to the time I saw her. This was her regular type of menstruation. Not a drop of blood was passed. Her family doctor was consulted and pronounced her pregnant again. With advent of her pain (six weeks after labor) she was given galvanism. Many opinions were expressed and many modes of treatment were adopted by several physicians, the most positive of which was that she had reached the menopause, because the doctor had on repeated occasions passed a sound into the cavity of the fundus. When she came to me she complained *only* of *crampy* pain in the lower abdomen, lasting three days, and recurring every twenty-five days, and absence of menstrual flow. Examination revealed an inconsiderable laceration of perineum and cervix, with complete occlusion of the uterine canal at the os internum. The uterus was not enlarged.

On April 7, 1894, twenty-nine months after labor, under ether-anesthesia, I forcibly established the uterine canal, and inserted a solid glass stem which was worn for nine weeks. There was no appreciable accumulation of blood in the uterine cavity. Two weeks later menstruation returned normally and painlessly, and has recurred every twenty-five days to the present time. I have seen many cases in which nature has shown herself a most capable conservative physician or surgeon, but never before to the same extent as is shown by this case, which of course illustrates the possible rather than the probable. I have been unable to find a similar recorded case. Three causes may have been active: injury at the time of delivery; injury from intra-uterine irrigation in the hands of the nurse, and injury from galvanism six weeks later.

A CASE OF HYSTERIA WITH ATAXIA CONFINED TO ONE LEG.

By CHARLES W. BURR, M.D.,
OF PHILADELPHIA;
CLINICAL PROFESSOR NERVOUS DISEASES IN THE MEDICO-CHIRURGICAL COLLEGE.

B. C. WHITE, male, 56 years old, upholsterer, was admitted to St. Joseph's Hospital on June 24, 1896. His history taken by my resident Dr. J. W. Colby is as follows: Previous health good, except that he had Chagres fever in 1890. He denies syphilis. He has taken alcohol daily, but in moderate quantities for years.

About one year ago he noticed "a peculiar sensation in the left leg as though worms were crawling over it." This lasted about two months and was followed by a feeling of extreme coldness, which still persists, in the entire left side. At times when walking he loses feeling in the left foot and is unable to locate its position. Three days before coming to the hospital, while walking in the street and without any preceding vertigo or headache or ill feeling of any kind, he suddenly fell unconscious as if shot. In a few minutes he regained consciousness and found himself sitting on a neighboring doorstep, where he had been put by some passers-by. He got up, walked eight squares, about three-quarters of a mile, to his home, went to bed and slept well. Next morning he was dull and confused and walked with uncertain gait, because as he says he was not sure of the position of the left leg. He has never before had a similar attack, been palsied, nor had convulsions.

The temperature on admission was $101\frac{1}{5}$° F., falling to normal in twenty-four hours and there remaining. He is a well-built, healthy-looking man. There are no objective signs of alcoholism or syphilis. While in bed or sitting he moves the arms or legs well, neither palsy nor ataxia appearing, but as soon as he gets upon his feet a certain motor-difficulty is seen. He has great trouble in standing, much increased by closing the eyes. The left knee and hip are alternately flexed and extended, and the trunk sways backward, forward, and laterally, but always to the left side. After a minute or two, if the eyes are shut, the movements of the left leg become quite wide in extent and he falls. In walking, which he can only do with the eyes open, he has great difficulty in putting the left foot where he wishes, the trouble being purely ataxic and not at all paralytic. He cannot follow a straight line, but always deviates toward the left. On the other hand he cannot turn around toward the left. So soon as he completely lifts the right foot from the ground and attempts to rotate the left upon the floor, the left leg begins to jerk, the body to sway, and he falls with some violence. He turns fairly well to the right. Under all conditions the ataxia of station is greater than that of motion. He can stand upon the right foot alone as well as, or even better than, upon both, and can stand upon the left only long enough to take a step with the right. There is no ataxia in the right leg, the disturbance of equilibrium occurring when he stands upon it, being caused by the irregular movements in the left leg. All movements of the arms are executed well. In short he stands and walks like a man drunk in one leg. He has, one may say, astasia abasia of one leg. There is anesthesia to touch, pressure, pain, and temperature over the entire left side from crown to toe, and stopping precisely at the middle line. Taste-sense is absent on the left half of the tongue, and there is partial deafness in the left ear. Dr. S. Lewis Ziegler examined the eyes and reports: "Pupils equal, moderately dilated and react well to light and with accommodation. Vision $\frac{20}{40}$ in the right eye, $\frac{15}{200}$ in the left. In the right eye there is no fundus-lesion and the field of vision is normal. In the left eye the disk is funicular and pale. There is some choroidal stippling with absorption of retinal pigment. The field of vision is concentrically reduced to a small area corresponding to the macula lutea.

The plantar, patellar, and cremasteric reflexes are normal on both sides. There is no local muscular wasting, nor any trophic changes in the skin or joints. Speech and voice are normal. His mental condition is good and he is not very emotional. The urine contains neither albumen nor sugar. There is no trouble with the bladder or rectum. Examination of the heart and lungs is negative. The pulse and respiration are normal.

On the third day after admission the hemianesthesia disappeared, but the contraction of the visional field of the left eye, the unilateral loss of taste and partial deaf-

ness, and the motor trouble continued. The last symptom rapidly improved and on leaving the hospital ten days later he was able to stand quite well, though still unable to turn sharply to the left.

The diagnosis needs no argument. It makes itself. The man has hysteria. The hemianesthesia, the contraction of the field of vision, the sudden return of sensation, the gustatory and auditory symptoms, the rapid recovery, all point unmistakably to it.

The case is interesting because hysterical ataxia confined to one extremity is rare, but more because it is an experiment made by nature which throws some light upon the mechanics of muscular coördination. We have a man completely anesthetic in arm and leg. In the arm all movements are perfect, in the leg all are widely incoordinate while standing, an incoördination which continues after sensation returns. With the eyes shut he knows perfectly the position of the arm actively or passively moved, but knows nothing of the position of the leg save when he looks at it. It must follow, as indeed has been repeatedly shown in many cases, both functional and organic, that anesthesia of the skin is not by itself sufficient to cause ataxia, and further that the so-called muscle-sense, by which we recognize movement and position, is not a mere modification of skin-sensation but something entirely different. What the elements that go to make up the muscle-sense are, and where the stimuli act, is still disputable. The simplest explanation is that it, like other sensations, is peripheral in origin, is the sum total of sensory impulses arising in and carried from the muscles, tendons, joints, and in much less degree, if at all, the stretched and folded skin whenever a group of muscles is in action. This is based upon the clinical fact that disease of the spinal cord or of the sensory nerves from the muscles, in the absence of any central lesion and without disturbance of common sensation, may cause ataxia, and further, because in health passive movements which certainly are not accompanied by any causative central act, either motor or sensory, are well realized by the subject. But it is maintained by some that the matter is not so simple, that instead of being peripheral in origin the sensation is central and is produced by or at least accompanies the cerebral action which results in movement of the extremity. There is no apparent reason in the nature of things why this may not be true. A motor nervous act in the brain may, for all we know to the contrary, have more than a motor result, it may itself be a sensory stimulus, and the sensations varying with each movement may each become unconsciously associated with a certain given movement, and finally be the means by which we know a movement is being made and its character. But none of this is proven and the means for its proof or disproof are not as yet at our command. For the present, therefore, since there is so much clinical and pathological evidence in favor of the peripheral origin of the muscle-sense, it is safer to hold, tentatively at least, to that view.

Wherever the stimulus which results in the muscle-sense may act, whether it is peripheral or central in hysteria, the disturbance of function is in the highest centers. Hysteria is not a thing pertaining to muscles, tendons, or joints, nor may we assume that there is any primary local trouble, nutritional or mechanical, in the center of coördination in the middle lobe of the cerebellum, but rather higher, probably in the prefrontal lobe. The trouble is more probably in the interpretation of the muscle-sense impulses than in the impulses themselves or the primary receptive center.

MEDICAL PROGRESS.

The Mortality of Harelip, With and Without Operation. FAHRENBACH writes in the *Deut. Zeit. f. Chir.*, vol. 40, p. 81, of 210 cases of harelip, which were operated upon in Göttingen from 1885–95. Rejecting the too minute classification of cases which some authors have made (Stobwasser enumerates thirteen different types), he has arranged his material in four groups, according as the cleft in the lip was single or double, and with or without complications in gums or elsewhere. The different operations performed are accurately described and illustrated, but an especial interest attaches to the mortality. The immediate results were satisfactory. In 166 cases the operation was entirely successful, and of the 210 cases only nine died—about four per cent., but when the cases were followed for a considerable time the author found the mortality to be discouraging. This is especially true of the cases with complications. Thus the cases of single harelip with complications showed a mortality in two weeks of 5.7 per cent., which in three months was doubled, and at the end of one year had risen to thirty per cent. of all the cases of this class. The death-rate for bilateral cases with complications was seventeen per cent. for two weeks, and the same for three months, but was over fifty per cent. at the end of a year. Including all the cases operated upon, the mortality at the end of two weeks was 7.5 per cent., at the end of three months 10.7 per cent., and 32.3 per cent. at the end of a year; and by deaths after one year these figures were raised to 41.8 per cent. So that according to these figures one-third of all children operated upon for harelip fail to live a year, and probably not one-half of them live to grow up. But these figures are to be compared not with those of healthy children, but with those of cases of harelip without operation. Just what the mortality among such deformed children is, is not known, but it must be high. For example: in one hospital (Rose, "On Harelip and Cleft Palate." London, 1891) fourteen per cent. of the patients with harelip died before they could be operated upon. Generally speaking the earlier the patients are operated upon the more of them succumb in the succeeding months, but this the author considers due to the fact that many of the children would not in any case be able to live. He is an advocate of an early operation (sixth to eighth week) for the lip, leaving until later the treatment of any deeper deformity which may be present.

Symptomatic Achillodynia.—In the *Deutsche Zeit. f. Chir.*, vol. xliii, p. 603, WIESINGER describes four cases of tuberculosis of the bursa Achillea upon which he has re-

cently operated. This disease has been given the name of "Achillodynia," though it is important to notice that the lesion is not confined to the bursa underlying the Achilles-tendon, but may involve the posterior part of the calcaneus. A vertical incision along the tendon is not sufficient, and to insure radical treatment the tendon must be divided one-half inch above its insertion, the cut being made obliquely or zigzag-fashion to facilitate its subsequent suture. Then the reflection of the cut ends exposes thoroughly to view the diseased portions.

Spontaneous Healing of Fistulæ in the Female Genital Organs.—BODEN has searched the literature of medicine for records of cases of fistulæ into vagina or uterus which have healed spontaneously. The result of his effort, as given in the *Centralbl. f. Chirurg.*, 1896, No. 38, has an important bearing on the question of operation in such cases, for he was able to collect 235 cases of spontaneous cure, and believes that he might have added to this number had the "Index Medicus" been accessible to him. The average duration of treatment before the fistula closed was three months, though in some of the cases a much longer period elapsed. The fistulæ were situated as follows in 235 cases: 132 vesico-vaginal; 27 vesico-uterine; 3 vesico-enteric: 3 ureteral; 52 recto-vaginal; 3 recto-uterine; 9 entero-vaginal; 6 entero-uterine.

Hysterical Hematemesis.—MATHIEU (*Gaz. des Hôpitaux*, No. 16). In hysterical patients not unfrequently a group of symptoms is observed which may be confounded with genuine hematemesis. In these cases the vomiting of a bloody fluid occurs usually at night after a previous feeling of distress and burning in the region of the epigastrium and esophagus. The quantity of vomited matter is usually from sixty to one hundred grams and looks like raspberry syrup. On standing it becomes darker in color, but never contains blood-clots. Traces of food are seldom found. The attack is but rarely preceded by nausea. The attacks occur monthly in women who show typical hysterical symptoms and also vague dyspeptic symptoms. As a rule, there is distention of the stomach with gas, and a spot susceptible to pain on pressure, a little to the right of the median line, and corresponding with the situation of the hypersensitive pylorus. Sometimes the attack occurs daily for several days or for a longer period, with an intermission of several days between the attacks. If after a few hours the vomited matter is examined, two layers may be observed. The upper layer is transparent and contains no solid particles; the lower layer is more opaque and contains mucous, red corpuscles, from which the color has more or less disappeared, white blood-corpuscles, and epithelial detritus. Saliva is generally present in considerable quantities in the vomited fluid, as is shown by the rapid metamorphosis which starch undergoes when exposed to its action. The source of the blood is doubtful. In several cases examined it could be traced to the detached mucous membrane of the mouth. This swallowed with the saliva most probably gives rise to the characteristic vomit. The source of the hemorrhage may also be in the stomach, though no serious lesions of that organ are generally found.

THERAPEUTIC NOTE.

The Treatment of Gonorrhea with Argonin.—ARTHUR GUTHEIL (*Deut. Med. Woch.*, 1896, No. 35). In the treatment of gonorrhea it is desirable to select a remedy, which, in the first place, destroys the gonococci; secondly, does not aggravate the inflammatory process; thirdly, does not injure the mucous membrane. Experiments with the preparations of zinc, lead, and tannin, have proven the absence of any germicidal properties whatsoever in these medicaments. Corrosive sublimate and potassium permanganate are efficient germicides, but also powerful irritants. Argentamin, a silver salt, recommended by Schäffer, is an efficient antiseptic, but fails to fulfil the second condition, namely, the least possible irritation of the mucous membrane.

The experiments with argentamin induced Röhmann and Liebrecht to furnish a soluble combination of albumin, silver, and an alkali, which, unlike argentamin and other preparations, should contain no free alkali, to the presence of which the corrosive action is due. Casein, which possesses acid properties and forms acid combinations with most bases, was found to be the most suitable substance. By the addition of silver nitrate to a solution of a sodium-preparation of casein and precipitation with alcohol, a soluble combination results. The precipitate thus formed is, after drying, a white powder, argonin (Liebrecht).

It is best to use a fresh preparation (one-half per cent.) and keep it in a dark bottle. Much stronger solutions have failed to produce any irritation. As argonin possesses but feeble astringent qualities it is often necessary to use other medicaments in combination. After the use of argonin, ichthyol has given excellent results.

Seventy cases of gonorrhea were subjected to the argonin-treatment by the author, the presence of gonococci having been first established. Of this number fifteen cases, in which the presence of gonococci was marked, were selected for special observation under the argonin-treatment. In these cases the author determined the exact time at which the gonococci ceased to be present in the discharge, as likewise the time in which the gonorrhea might be considered as entirely cured. After eight or nine days of treatment the gonococci ceased to be visible in the discharge. From this it is not to be understood that the gonorrhea was entirely cured. On the contrary, after the use of argonin twenty-one days on the average were required under the application of astringents, ichthyol especially, before the gonorrhea was completely healed.

In conclusion, the author finds that argonin is not only non-irritative, but also gives rise to no subjective symptoms. As is the case with all medicaments, a case occasionally presents itself showing special idiosyncrasies. To sum up, the author recommends argonin for all cases of gonorrhea that come under the observation of the practitioner. It destroys in a comparatively short time, without giving rise to any irritation, the gonococci. This is already a great advance in the treatment of gonorrhea, as it precludes the supervention of any complications. In confirmation of this fact it may be stated that of the seventy cases only one manifested symptoms of epididymitis.

SATURDAY, NOVEMBER 14, 1896.

THE WISCONSIN DIPLOMA-MILL.

It is a disgrace to the civilization at the close of the Nineteenth Century that any State of this Union should be so unmindful of the health, the welfare, and the lives of its citizens as to charter institutions and empower them to confer the degree of doctor of medicine on any person without restriction in regard to study, to mental, or moral fitness, or to any other possession, except that of a variable amount of money. Yet such is the state of affairs to which we bear witness to-day. A few weeks ago we called attention, editorially, to a Western diploma-mill, known legally as the Illinois State Health University. We pointed out in detail that, according to its announcements and circulars, the function of this mill is to furnish diplomas to men and women who have neither preliminary education nor the time to attend "Monopoly" medical colleges, but who can scrape together $75 or $100 for the purchase of a diploma which apparently gives equally with the graduate of the most scientific institutions in the land the right to administer professionally to the sick. Since our editorial on the subject we have received letters from various parts of the country, all of them pointing out that the impostor of whom we wrote was but one of a number doing apparently a lucrative business in Chicago. Some of our correspondents have inclosed communications with which they have been favored from the president or the secretary of the Wisconsin Medical College of Milwaukee, the correspondence department however being in Chicago, where all moneys are received and from which the diplomas are mailed. In other words, a Chicago sharper has pulled the wool far down over the eyes of the Wisconsin legislators, and they have granted him a charter of a medical college. His "goods"—beautifully engraved diplomas in the Latin tongue—are made in Milwaukee, and Chicago is his selling-center.

The organizer of this toadstool medical college has elected himself president and his wife secretary. Appreciating the fact that it is usual to have masculine names down as officers, and yet unwilling to have the matter get beyond his own fireside, he gives only the initial letter of his wife's first name and spells out the middle name which carries with it no significance of sex.

One mode of operation of this medical cormorant is to take the Medical and Surgical Directory and ferret out the names of those who are practising medicine under the certification of licensing boards, but without titular accompaniment. These he addresses in the glowing language of Chimmie Fadden, which interpreted reads: "We are selling diplomas at reduced rates, what good reason can you offer for not taking advantage of our bargain-counter?" Another method is to get the addresses of first-year medical students in the cheapest medical colleges, and submit a similar question to them: "Why attend a medical college for four years when the same privileges can be given to you by our college without attendance?" Unfortunately, and with sorrow, be it said, there are dishonest people enough to make this nefarious business pay.

In a State disgraced by such an institution, it becomes the first duty of each physician to see that his legislator is made to realize the fatal mistake of allowing the charter to remain unre-

voked. It is none the less the duty of health-boards to prosecute the holders of all these trade-diplomas.

THE TREATMENT OF BOVINE TUBERCULOSIS IN DENMARK.

DR. B. BANG of Copenhagen in *Deutsche Zeitschrift für Thier-Medizin und vergleichende Pathologie*, vol. xxii, relates some of his observations and deductions based upon 54,000 cases of tuberculin-application. In 1893 the Danish government enacted a law appropriating an annual grant of $13,500 for a period of five years for the extermination of bovine tuberculosis. The fundamental experiments, leading up to this grant, were conducted at a farm at Thurebybille, on the island of Seeland, that had been rented by a company of stock-raisers who were attempting to rear and supply for the general market a good class of milch-cows of the red Danish breed.

He says of Denmark, that while in that country stock-raising and dairying have for years been the chief source of national prosperity, the people have been averse to radical measures for the suppression of "the white plague" of tuberculosis. After considering the various methods employed, particularly those of Massachusetts, which he terms "drastic;" and the proposed French requirements of killing within a year all imported cattle that show a reaction from the tuberculin test—a plan that in his opinion is too rigorous and inclined to work the financial ruin of many cattle-owners—he concluded that Denmark was too poor a country for the destruction of every reacting animal. Accordingly he offered a plan of action that looked to the gradual elimination of the disease by applying the test only to young cattle. Moreover, an inducement was offered to cattle-owners by making the application and supervision of the test free to them, provided they would guarantee to separate the healthy animals from those which showed reaction. The limitation of the test to young cattle was made for the following additional reasons: first, because it was seen that the raising of new healthy herds was most important; second, because at that time tuberculin was very dear and the quantity to be consumed was of no slight economic importance.

The rearing of calves born from cows that reacted to the tuberculin-test, but otherwise apparently healthy, was deemed advisable because the large majority of such calves were found to be free from the disease. The precaution, however, was taken to immediately remove these calves from their mothers and rear them on sterilized milk.

Tuberculosis-investigations have made it highly probable that the coöperative dairies often contribute to the spread of the disease. The patrons receive in return for their milk skimmed milk for feeding calves and swine. It is understood, of course, that they do not receive their own milk, but a part of the mixed milk. In case the milk of another patron comes from a tuberculous cow, the danger is at hand that in this manner the disease may be communicated to a healthy herd. That this actually happens is proved by the common observation that all grown cattle of a herd may be found healthy, while various calves and heifers react. Fortunately skim-milk is almost everywhere sterilized before being distributed, but it is frequently not heated to a sufficiently high temperature.

From the observations described it must be apparent that infected milk has much to do with the spread of tuberculosis among young animals. By cooking or warming the milk at a temperature of 185° Fahrenheit, sure protection may be easily obtained. The calf, however, can scarcely dispense with the colostrum during the first day of its life, but from the second day cooked milk is easily digested. At Thurebybille all calves were fed very successfully with cooked milk from the second day on. The colostrum was warmed to 65° C. (149° F.). This temperature does not, indeed, kill tubercle bacilli; but weakens somewhat their virulence.

Collected evidence has abundantly proved that by following the simple rule of feeding calves only with cooked or highly pasteurized milk gives the very best results. On farms where this method was used and careful sequestration was practised, all calves were healthy, even where tuberculosis had widely spread among the grown animals.

In the case of swine which are largely fed with skimmed milk, whey, or buttermilk, the "feeding tuberculosis" plays an important part. Tubercu-

losis in horses is not rare in Denmark, doubtless because of the extended use of milk in fattening young horses intended for the market. This usually appears, in "feeding tuberculosis," in the form of intestinal ulcers, and very large deposits in the mesenteric glands, sometimes also in the peri-pharyngeal glands, and accompanied by secondary deposits in the lungs.

THE DIAGNOSIS OF TYPHOID FROM BLOOD-SERUM.

The scientific investigations of Pfeiffer upon the specific bactericidal substances developed in the blood of animals, immunized by injections of typhoid bacilli, have given rise to unexpected practical results in furnishing a means of diagnosis which bids fair to be as reliable and practical as the examinations now made in cases of suspected diphtheria and tuberculosis.

Widal and others in France discovered that these specific substances were present regularly in the blood of typhoid patients as early as the seventh day, and sometimes earlier. They found that if to a drop of blood-serum, or to a drop of water containing a solution of dried blood from a typhoid patient, a moderate number of typhoid bacilli were added, a very peculiar reaction occurred, which was readily observed under the microscope. The typhoid bacilli were found to gather themselves in clumps, and thus entangled to cease their former active movements. As a rule this took place within five minutes, and always within a few hours. With no other blood than that from those who have suffered from, or are suffering from, typhoid fever will the typhoid bacilli give this reaction.

Johnston of Montreal has simplified the technique so that any one can collect the blood for examination, and if he is familiar with simple bacteriological work, can himself observe the reaction. The blood is obtained upon a clear glass slide from a needle-prick of the ear or finger of the suspected case. It is allowed to dry, and thus sent or carried to the laboratory. It will give this reaction even after having been kept for several days.

At the laboratory a loop of a bouillon-culture of absolutely reliable typhoid bacilli is placed upon a clean cover-glass, and to this is added a large loopful of a watery solution of the dried blood-specimen. The cover-glass is now inverted over the concavity of a hollow slide and sealed at the edges with melted vaseline. Under the microscope, with a high-power dry-lens, or with a one-twelfth oil-immersion, the rapid clumping of the bacilli in the hanging drop can be observed.

At the New York Health Department laboratory there has been examined in this way the blood of thirty-four cases of typhoid fever. In thirty-three of these characteristic clumping of the bacilli occurred either immediately or within a few hours. In one, a case already convalescent forty days, no reaction appeared. The late date at which the blood was taken, or a possible error in diagnosis, may account for the failure.

In fourteen cases of other diseases this clumping did not occur at all, or to such a slight degree as to be easily distinguishable from the typhoid cases. Some of the doubtful and mild cases gave as good reactions as the more severe cases.

This is a confirmation, therefore, of the claims of Widal, Johnston, and others, that it is possible to make a correct, positive diagnosis in the great majority of cases, and perhaps, with greater experience, in all, by the reaction which takes place between the typhoid bacilli and the blood of the suspected case. If there is no specific reaction in a case sick over a week, the diagnosis of typhoid fever must be excluded. If a marked reaction occur, then, unless the patient had had an attack of typhoid fever within at farthest ten years, the case is typhoid fever. The few in which a slight reaction only occurs, must be left doubtful until later examinations clear up the case. The Health Department of New York City is so certain of the practical value of these examinations in doubtful cases that it has already arranged methods for collecting and reporting, without charge, upon blood-smears from suspected cases, as described in the announcement which appears in this issue of the Medical News.

Wm. H. Park, M.D.

ECHOES AND NEWS.

Icelandic Lepers.—Iceland, with a population of 75,000, has 400 lepers, but no attempt has been made to alleviate their condition or prevent the spread of the disease.

The Rush Monument.—One hundred and fifty-nine dollars has been subscribed to the Rush Monument Fund since April 17. The sum now on hand is $3886.39.

Distress in Ireland.—The failure of crops, owing to persistent rains in Ireland during the past season, brings the inhabitants face to face with famine and its constant companions, disease and pestilence.

Maternal Impressions.—A hen in Vermont, after looking at a three-pound potato grown by a neighbor of her owner, went to the barn and laid an egg measuring 8½ by 6½ inches.—*Medical Record.*

The Commercial Travelers' Home.—A fair will be held in Madison Square Garden, New York, December 15–29, to raise $150,000 with which to complete the National Commercial Travelers' Home at Binghamton, N. Y.

Pure-beer Investigation.—A commission appointed by the British Treasury is making inquiry as to the purity of materials used in the manufacture of English beer. The proceedings of this commission up to the present time are held in contempt by *Food and Sanitation.*

Improvements at Bellevue Hospital.—Plans were filed at the Department of Buildings of New York City, last week, for additional buildings to be erected in connection with Bellevue Hospital, at an estimated cost of $130,000. A water-tower is also to be built west of the City Hospital on Blackwell's Island.

Dogs to be Banished.—Street-cleaning Commissioner Waring last winter directed the attention of the Board of Health of New York to the insanitary, if not dangerous, habit of permitting dogs to frequent the streets and sidewalks. The advantages of compelling their owners to confine them to private premises are now under the consideration of the sanitary committee.

Promotions in the Medical Faculty of Johns Hopkins University.—The trustees of Johns Hopkins University at their last monthly meeting advanced Dr. Lewellyn F. Barkar to Associate Professor of Anatomy, and Dr. William S. Thayer to Associate Professor in Medicine. Both gentlemen had amply demonstrated their fitness for such honors while serving as assistants in these departments.

The Japanese Intestine.—Finding rice was better utilized by the Jap than the European, it occurred to Dr. Scheube of Kioto that some racial difference in the intestinal anatomy might supply the explanation. Professor Taguchi, after measuring the intestines of twenty-five cadavers at Tokio, now asserts that, after making proper deductions for variations in stature, the Japanese intestine is one-half longer than that of the European.

An Altruistic Queen.—Queen Amelie of Portugal interests herself personally and effectually in improving the hygienic condition of Lisbon and in providing medical and surgical attendance for the poor. To her efforts was due the early introduction into Portugal of the serum-treatment of diphtheria. She founded, and with the aid of her Court ladies maintains, an institution called the Dispensaria de Sua Majestade la Rainha, where sick children receive care and treatment under conditions as favorable as exist in the best private hospitals.

Bacteriological Aspect of the Plague in Bombay.—Drs. Childe and Surveyor are reported to have found the bacillus described by Kitasato in the urine, the sputum, the serum from the bubo, and in the blood of a plague-stricken patient in Bombay, and also in the organs of rats and mice that are dying in large numbers throughout a certain district. Inoculations from the blood and organs of persons who have died of the plague, or from pure cultures, invariably proved fatal to healthy rats in about sixty hours. The plague is said to be spreading in India.

The New York Academy of Medicine.—The Academy is about to celebrate the semi-centennial anniversary of its organization. Three separate committees have been appointed to take the matter in charge and make definite arrangements. The plan of the celebration embraces a program of public exercises in either Carnegie Hall or the Metropolitan Opera House. In addition to appropriate remarks of representative Fellows of the Academy, an address will be given by some distinguished citizen. After these exercises a reception will be held in the Academy itself, where refreshments will be served.

"Suggestionized" Witnesses.—A man was recently tried at Munich, Bavaria, for the murder of three women. Witnesses were called to prove that the prisoner had attempted to enter their houses for purposes of robbery. Counsel for the defendant asked if it were not the case that in sensational affairs which excited public feeling very much, individuals, even of normal dispositions, might "suggestionize" themselves with regard to events they believed they had seen, and whether, through unusual association of ideas, mental images might not become confused. The expert medical opinion given did not uphold this defence.

The Anti-diphtheritic Property of Human Milk. — Drs. Schmidt and Pflanz in the *Klinische Wochenschrift* report the results of experiments made to determine the anti-diphtheritic properties of human milk. The antitoxins of the milk pass into the digestive tract of the suckling child and thence into its circulation, without undergoing any change. It is generally recognized that suckling children rarely suffer from diphtheria. The blood-serum from the placenta after the severance of the cord was also examined for purposes of comparison. The antitoxins contained in the blood of a lying-in woman are less in quantity than those in the milk.

The International Medical Congress.—"We are asked to state that the organizers of the surgical section of the forthcoming International Medical Congress at Moscow propose to collect statistics of the administration of anesthetics in all countries during 1896. They will therefore be glad to receive information from any member of the profession in a position to give it, on the following points: (1) Number of administrations from January 1, 1896, to January 1, 1897; (2) the anesthetic used; (3) number of

deaths. Replies should be sent not later than July 1, 1897, to the secretary of the surgical Section, Dr. F. Rein, Maison Schischkov, Malaja Dmitrovka, Moscow, Russia." —*Brit. Med. Journ.*

A Disclaimer.—Dr. J. McFadden Gaston is justly indignant that his name should have been associated with an article headed: "Making a Trap-door in a Human Being," which appeared in a recent issue of one of New York's unmentionable Sunday newspapers. The garbled text and figure were appropriated from a medical journal, to which his paper was contributed. No such feelings, however, seem to ruffle the placid composure of a prominent editor of a leading medical journal who figured conspicuously in the last Sunday issue of the same newspaper. Possibly he has fallen a victim to the same methods that were practised upon Dr. Gaston and in his helpless position deserves equal sympathy.

Roosevelt Hospital Alumni.—A reunion and reorganization of the Alumni of the Hospital into an active body, for scientific work and social intercourse, was held Monday night, November 2d, in the Administration Parlors of the Roosevelt Hospital. Nearly all the old graduates from the various divisions were either present or sent letters of regret, the most notable absentee being Prof. Geo. L. Peabody. Officers to serve a year were elected: President, Dr. E. B. Cragin; vice-president, Dr. F. J. Brockway; secretary, Dr. H. C. Hatton; treasurer, Dr. E. P. Mallett. Dr. Chas. McBurney was unanimously elected an honorary member, and at his invitation a most elaborate collation was served by the Metropolitan Club in the various anesthetizing-rooms and corridors of the famous Syms operating-theater.

Popular Science.—A correspondent of the *Lancet*, who conducted a small Röntgen-ray gallery at a bazaar, encountered many gems of unconscious humor, of which the subjoined are examples: An elderly gentleman of prosperous appearance objected that the show was not "up to date," as he had "read somewhere in a newspaper that now you can see the liver palpitating and the heart circulating." A young and anxious mother asked to see if her little boy had really swallowed a threepenny-bit, as he was uncertain himself. She had read in the papers that a great doctor, Sir Something Blister, in a speech in a large meeting in Liverpool, a little while ago, said that a halfpenny had been seen in a boy's "sarcophagus!" A girl of the domestic-servant class asked the curator in confidence to "look through her young man unbeknown to him, while he looked at the picture, to see if he was quite healthy in his internals."

Changes in the Pupil in the Insane.—At the recent meeting of German alienists at Heidelberg, Dr. Soemerling read a paper with the above title. He attaches little importance to a difference in size of the pupils. Of all conditions of the pupil in the insane, the loss of reaction to light is of the utmost importance. In 3010 cases of progressive paralysis, it was found to be present in sixty-eight per cent. The sudden and quick dilatation of the pupils is sometimes present in general paralysis, but this occurs also in the healthy. Hippus is rare in paralysis. Except in general paralysis, the loss of light-reflex in the pupil is uncommon. Among 9160 insane the symptom was present in 1639 cases, and of these 1524, or ninety-two per cent., were cases of general paralysis. In syphilis, also, this condition of the pupil is sometimes present without evidence of any other morbid condition. Its occurrence after injuries to the head alone is very doubtful, and it probably does not occur in simple and uncomplicated hysteria. If the loss of light-reflex is not a precursor of tabes dorsalis or general paralysis, it at least indicates a profound disturbance of the nervous system, and it may be present long before any other morbid phenomenon manifests itself.

Obituary.—Dr. Francis H. Rankin died at Newport, R. I., November 9th. Dr. Rankin was born in Fishkill-on-the-Hudson, in 1845. He was graduated from the New York University in 1862. He was acting assistant surgeon in the Prussian army during the Franco-Prussian war. He commenced the practice of medicine in New York in 1871. He was connected with the New York Hospital for Diseases of the Nervous System, the Manhattan Eye and Ear Hospital, the Demilt, Children's and Northeastern dispensaries and other institutions. In the summer of 1876 he went to Newport.—Dr. Henry A. Mott died in New York, November 8th. Dr. Mott was born at Clifton, Staten Island, forty-four years ago. He entered Columbia College, taking a course in the School of Mines. After receiving his degree of mining engineer in 1873, he took up the study of technical chemistry. In 1881 he was made Professor of Chemistry in the New York Medical College and Hospital for Women. He was employed for three years by the Government as the examiner of the food purchased by the Indian Department. He was the chemist of the New York Medico-Legal Society, and belonged to many American scientific societies. He was the author of several scientific works.

CORRESPONDENCE.

"THE BUSINESS END OF IT."

To the Editor of THE MEDICAL NEWS:

DEAR SIR.—I have just finished reading the article in your issue for October 24th, with the title which heads this letter. I write to offer my hearty congratulations, and to say that the author strikes a key-note which ought to ring through our profession and accomplish much good. I could only differ in the matter of the length of interval between bills, upon which point I am even more radical. I send mine monthly.

When I began practice fifteen years ago I sent out bills semi-annually. In time I saw the folly of this, a method inherited from my grandfather, an old-time physician, and graduated into presenting them four times a year: December 1st, March 1st, June 1st, and September 1st. This was an improvement—a step in the right direction. And for those who prefer the ninety-day interval, the months I specify are better, perhaps, than others. If the

doctor's bill is received amid the swarm sent into each household upon January 1st, it is snowed under, and is fairly certain of neglect; whereas, on December 1st, a month earlier, and before Christmas expenses, matters are otherwise. Again, the date June 1st is preferable to July 1st, because by the latter time the paterfamilias is probably already paying heavy hotel bills for his family's summer outing; and a bill so feebly urged as the doctor's can well be placed on file until the autumn—or later. One is reminded of the deacon of accumulative instincts, who, upon being reproached with his systematic neglect of the contribution-plate, explained that the Lord did not press him so hard as he did his other creditors.

After a few years' further experience the writer concluded to try the plan of rendering accounts, upon strict business principles, on the first day of every month, and of having engraved upon his bill-heads: "Bills presented monthly"—by way of indicating that nothing invidious is to be inferred by the patient in any instance. In no case, as yet, have I induced death from heart-failure at the shock of finding the physician to be also a man of business. Moreover, it is unquestionably easier for patients to pay, and for the doctor to collect $10 twelve times a year than $120 once a year. By this plan, and with ordinary prudence, I do not have above five per cent. of bad debts annually—which is a remarkable low percentage for a physician.

Most doctors are their own bookkeepers. As a class they do not earn their salary as such, and should discharge themselves. I fear that Dr. Miles' wise essay will fail of accomplishing so much as otherwise it may, unless this feature of the matter shall be corrected. The tired, overworked doctor will always postpone until that more convenient time which so seldom comes, this particularly unpleasant duty. I firmly believe that it will pay all practitioners, except those just beginning, and with small practices, to hire an accountant by the year; turning over to him the pocket-daybook at the end of each month; and giving him a schedule of prices for certain work, as a general guide. The bills thus prepared are to be examined in review, just before mailing, by the doctor, in the accountant's presence, and if desired altered from the schedule.

This naturally brings up the question of our fees—which need agitation if ever a topic did. Even the best brains of our profession are not paid as they ought to be, as, for example, eminent lawyers are. The writer regards such men as *invariably underpaid*. If by some simple suggestion—but born of genius wedded to experience—a brain is saved by the neurologist from insanity, a mind that otherwise must have entered oblivion, then a fee of a hundred thousand dollars, in the case of a millionaire, would be small indeed for that work. The specialist would still be underpaid, would still deserve our commiseration; but not so much so as usual. In most such instances that brain-specialist is lucky if he adds a twenty-dollar fee to his slender bank-account. And were he instead to charge a tithe of the first-named sum, the man of wealth would use his restored mentality in devising lurid invectives to fit this particularly atrocious case. On the other hand, a lawyer who should win some transcontinental railway-suit for this same millionaire would name a fee of five figures with calmness, and it would be paid as a matter of course, and without unseemly wrath. Who shall say that this picture is overdrawn?

I have small patience when I hear, as I have repeatedly done, the argument used that we should charge all people alike, without regard to their financial condition; that if we charge Mr. Smith fifty dollars for setting a broken bone, we have no right to charge Mr. Jones five hundred dollars for the same thing. Still less do I rejoice and give thanks when the speaker is a doctor (there actually are such) who maintains that his brother physician—in the instance of a given wealthy patient whom he has cured—has "overcharged."

Pardon a slight divagation. Once upon a time the Emperor William I. of Germany, while walking through a market, priced the eggs offered by a certain old woman. Startled at the sum she named per dozen, he exclaimed: "Can it be that eggs are indeed so high?" To whom returned the *handelsfrau*: "Nay, Your Majesty, eggs are plentiful enough. It is kings who are scarce." Now, all can see the gross injustice herein attempted upon an inoffensive and defenseless monarch. But the fable, as I maintain, does not apply to our case. We are not selling our brains over a counter at so much per thought, or per dozen thoughts. The Smith-Jones argument above-mentioned comes with ill grace when directed against a profession which serves the poor without money and without price, to such an extent that one-fourth of the population of this great city of New York get their medical attendance free! This is literally true. Those who can pay should, as I believe, do so somewhat in proportion to the extent of their means; at least for operative and for consultative work involving unusual experience and ability.

One further point, often neglected: The family doctor can better judge than the expert, whom he calls in consultation, as to the patient's fortune, and, therefore, as to what would constitute a fair fee in a given case. It is my custom to submit my proposed charge first to the doctor, and be guided by his decision in this matter. Should the operator offend the patient by the size of his bill, the doctor who has recommended him may suffer a vicarious punishment from the subject, subsequently. Consequently the arrangement just named seems but courteous to the family medical attendant.

Once more let me convey hereby to Dr. Miles my compliments, congratulations, and personal thanks for the good work he is doing.

Respectfully,

ROBERT H. M. DAWBARN.

THE DOSAGE OF NITROGLYCERIN.

To the Editor of THE MEDICAL NEWS.

In reference to the paper entitled "The Dosage of Nitroglycerin," which appears in the current issue of the MEDICAL NEWS, I beg to call the writer's attention to previous communications by myself upon this subject.

These appeared in the *Philadelphia Polyclinic* of December, 1888, and *Therapeutic Gazette*, September, 1893. In these I record a case of my own, taking twenty grains of nitroglycerin daily without more decided effect on the blood-pressure than had originally been produced by an initial dose of one one-hundredth of a grain six months previously. This case, although quoted by other writers, has evidently escaped the attention of Dr. Hare and Dr. Whitaker. In my paper in the *Therapeutic Gazette* on "Tolerance to Nitroglycerin Easily Acquired," I refer especially to the great difficulty attending its administration in cases in which it is most indicated—those of unduly and obstinately raised blood-pressure—in order to obtain a maximum effect with minimum dosage. Such doses as Dr. Armstrong records, as in the case of my own, are highly impracticable and dangerous, not through effect upon the blood-pressure, but through the influence of the drug upon the blood itself. In cases of such extraordinary tolerance as Dr. Armstrong records, other modes of influencing high tension, as remarked in the second communication referred to above, must be resorted to. It is well known that nitroglycerin, in common with the nitrites, in full doses, partially or completely, arrests the oxygen carrying power of the red blood-corpuscles, producing a condition of methemoglobin. This effect is of course brought about irrespective of action upon blood-pressure, and is a condition to the ill effects of which tolerance cannot be acquired. Curiously, little attention is given by therapists to this action of the drug. It is not considered that the drug cannot be given immoderately, even though it does not unduly flush the face or cause headache. In my case, in which twenty grains of nitroglycerin were taken daily, a most decided dusky hue of skin was produced by much less doses, indicating the effects upon the oxygen-carriers of the blood. These effects cannot but be harmful, and when the drug is long continued may result in great injury.

Very respectfully yours,

D. D. STEWART.

THE USE OF SURNAMES IN MEDICAL LITERATURE.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I was very much interested in Dr. James Tyson's communication in your journal of November 7, 1896, on "the use of surnames only in citing authorities in medical literature."

As an author on historical as well as medical subjects, I beg leave to suggest that not only ought Christian names to be mentioned, but the place where, and the time when, they lived be also added. It would cost the author a little more trouble, as Dr. Tyson aptly remarks, but an unselfish author must expect to take the trouble of saving the inquiring student unnecessary labor of finding out what he himself should have stated at the time.

Yours truly,

R. C. M. PAGE, M.D.

NEW YORK, Nov. 9, 1896.

ANNOUNCEMENT.

ARRANGEMENT OF THE NEW YORK BOARD OF HEALTH FOR THE DIAGNOSIS OF TYPHOID.

To the HON. CHARLES G. WILSON, President of the Board of Health.

DEAR SIR: I desire to direct the attention of the Board to a new laboratory-method for the diagnosis of typhoid fever which, judging from the data available at the present time, promises to be of very considerable practical value in the diagnosis of early or ill-defined cases of this disease.

The investigations of Pfeiffer and Widal have shown that the blood of persons suffering from typhoid fever, when mixed with active cultures of the typhoid bacillus, has the power of arresting the active movement of these organisms, and of producing peculiar and characteristic clumping of the bacilli. It has been shown that this reaction occurs frequently very early in the course of the disease; that it is found throughout its course, during convalescence, and often for a considerable period after complete recovery. It does not occur with other organisms than the typhoid bacillus, and it does not occur with cultures of the typhoid bacillus when the blood of persons suffering with other diseases is employed. As has been shown by Widal and Johnson, this reaction occurs as well with specimens of dried blood as with fresh blood, and thus can be employed practically for the diagnosis of this disease in municipal laboratories. Observations on this matter which have been in progress in the laboratories of this department for some time past, have thus far confirmed the conclusions of previous investigators.

In order that more numerous data shall be at the command of this department, and that physicians of New York may at the earliest moment have facilities for testing the reliability of the observations thus far made, I should respectfully recommend that arrangements be made to place facilities for such examination at the command of all physicians in this city, it being distinctly understood that this action of the department is for the purpose of gaining information on this important subject, and at the same time of placing at the command of physicians opportunities for observing the results. If the data already obtained are entirely confirmed by subsequent observations, this method will undoubtedly prove of great service in the diagnosis of early and obscure cases of typhoid fever.

Should this action be determined upon, circulars of information as to the method of collecting blood and slides for this purpose may be left at the depots already established for the collection of diphtheria-culture tubes and the distribution of diphtheria-antitoxin.

Respectfully submitted,

(Signed) HERMANN M. BIGGS,
Pathologist, and Director of the Bacteriological Laboratories.

NEW YORK, November 6, 1896.

The following resolution was adopted by the Board of

Health of the Health Department at a meeting held November 6, 1896:

RESOLVED, That the recommendations of the Director of the Bacteriological Laboratories of this Department contained in the communication dated November 6th, be and are hereby approved, and that he is hereby authorized to place facilities at the command of physicians of this city for the diagnosis of cases of typhoid fever, in accordance with the method prescribed in said communication.

NOTICE TO PHYSICIANS.

Circulars of information regarding the method employed, and slides for collection of blood, may now be obtained at the various druggists where diphtheria-culture tubes are kept. Physicians desiring to make use of this method in the diagnosis of early or obscure cases of typhoid fever can procure these and, after collection of blood as described, may leave the slides with the data relating to the case at the various depots. They will be collected each day, examined the following day, and the report of the result forwarded to the physician.

(Signed) HERMANN M. BIGGS,
Pathologist, and Director of the Bacteriological Laboratories.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON GENERAL MEDICINE.

Stated Meeting October 20, 1896.

REYNOLD W. WILCOX, M.D., Chairman.

W. GILMAN THOMPSON, M.D., read a paper on

EXPERIENCE WITH THE TREATMENT OF ENTERIC FEVER BY COLD TUB-BATHS.

In describing the Brand method of treating typhoid fever by tub-baths, the author said that the baths were given at an average temperature of 70° F., and an average duration of fifteen minutes, and that they were indicated as often as the temperature reached 102.5° F. Of course, due regard should be had to proper hours for sleep and rest, and ordinarily the baths were not to be repeated more frequently than once in three hours. He emphasized particularly the very great importance of having the patient properly rubbed by two attendants, from the very commencement of the bath. The patient's chief complaint is usually the shivering produced by the baths, but this could be largely controlled by administering half an ounce of whisky, half an hour before the bath, and by due attention to the rubbing of the body-surface. It is not uncommon to find that the shivering is much less severe after the first few baths, but should it be especially troublesome, the bath should be given a little higher temperature, and the patient given hot drinks freely. These baths were certainly not pleasant to the person receiving them, but the patient soon recognized their beneficial effect on the circulation, and particularly their tonic effect on the depressed nervous system. This, indeed, was their important function. Ordinarily from fifteen to twenty-five baths would be required in a case of typhoid fever. The average reduction of temperature effected by one of these baths is between two and three degrees Fahrenheit. Osler had recently reported that in the Johns Hopkins Hospital the death-rate had been 7.1 per cent., and Wilson of Philadelphia had reported a death-rate from the same method of 7.25 per cent. It had been objected that this treatment was not only barbarous, but tended to increase the liability to intestinal hemorrhage, but the latter was not substantiated by the facts. He thought it was safe to resume the baths when the patient had had one normal stool after an attack of intestinal hemorrhage. The author's conclusions were: (1) Cold-tub bathing does not ordinarily shorten the duration of enteric fever; (2) it does not prevent the recurrence of relapses; (3) it does not prevent the occurrence of many of the ordinary complications of the disease, most of which are less severe than by other treatment; (4) it does not preclude the simultaneous use of any other recognized method of treatment; (5) it may be safely employed in all cases except those actually having at the time severe intestinal hemorrhage or pneumonia; (6) it is rational because of its action in stimulating the nervous system, and because it regulates the metabolic processes of the body, and increases the vital resistance; and (7) when begun in the first week there is almost a certain prospect of the disease running a much milder course, and in the severer cases the mortality is reduced approximately one-half.

MORRIS MANGES, M.D., presented a paper on

THE ANTITOXIC AND THE ANTISEPTIC METHODS IN THE TREATMENT OF TYPHOID FEVER.

(See Page 541.)

DISCUSSION.

DR. FRANCIS DELAFIELD opened the discussion with the statement that in his opinion the tub-bath method of treatment was the best at present known, and that it should be begun early, without waiting for any hyperpyrexia. As this method was not capable of application in all cases, he had experimented with other plans of treatment. He had recently tried the Woodbridge method of treatment in thirty cases. This consists in giving small and frequently repeated doses of calomel, podophyllin, eucalyptol, and carbonate of creosote. He had soon found that the calomel was causing many sore mouths, and had accordingly substituted in some cases the sulphate of magnesium for the calomel. There had been no relapses in this series of cases, and of the four deaths that had occurred, three were of patients who had been under treatment eleven days or less. It would seem, therefore, that this treatment somewhat shortened the duration of the disease in the mild cases, although showing no control over the severer ones.

DR. A. BRAYTON BALL said that the reason the first trials of the Brand method had been unsatisfactory was because the proper rubbing of the body-surface had been omitted. One very important effect of these baths was to cause gasping or forced inspirations. There was no need to discontinue the baths during menstruation, for the total immersion of the body in this way was very different from placing the feet in cold water. It was a mistake to sup-

pose that the object of these baths was to reduce the body-temperature. The more he saw of this treatment the better he was pleased with it.

DR. W. P. NORTHRUP said that he had started in to make a very careful trial of Fraenkel's injection-treatment, but, with the exception of the first case, the patients had done so badly that he had been forced to discontinue it and resort to the baths in order to save their lives. He was thoroughly convinced of the great value of the Brand method, but wished the treatment could be modified in some way so as to keep the extremities from becoming so cold.

DR. LOUIS WALDSTEIN said that he had often pondered over the question of the possibility of aborting typhoid fever. Although our present knowledge was opposed to this view, such well-known clinicians as Wunderlich and Friedrich had long insisted that this could be done, and the absence of means of making a positive diagnosis at a very early stage prevented us from answering the question absolutely in the negative. All physicians were familiar with a class of cases not infrequently met with in private practice, called "continued fevers," which yielded easily and quickly to calomel and a liquid diet. Recently he had seen such a case relapse after two or three weeks, and the second illness pursued the typical course of typhoid fever.

DR. RICHARD C. NEWTON of Montclair, N. J., said that years ago he had observed in the army a number of cases of what was called "the mountain-fever," and he had not been a little surprised to find at autopsy on one of these patients the typical lesions of typhoid fever. He felt quite sure that he had been able occasionally to abort typhoid fever by the administration of calomel.

DR. A. PALMER DUDLEY said that it did not seem to him that the Brand method was rational, as, aside from its being cruel, it produced considerable shock, and failed to accomplish a most important part of the rational management of this disease, *viz.*: the elimination of the poison. Death in typhoid fever was usually due to heart-failure, and, in his opinion, these tub-baths were well calculated to cause the heart to fail. To his mind, it was more rational to administer to a typhoid-fever patient citrate of magnesia, and in this way wash out the intestine, and at the same time cause the elimination of the poison by exciting osmosis. Enemata certainly could not reach beyond the ileo-cecal valve. In addition to the citrate of magnesia the patient should be given quinin and nux vomica to combat the tendency to heart-failure, and the diet should consist entirely of milk.

DR. S. BARUCH said that the Brand treatment was intended so to increase the vital resistance that the patient should be able to resist the toxemia of the disease. Brand insisted that this treatment should be begun before the fifth day of the disease, but that would be obviously impossible in hospital-practice. In private practice it was his own custom to begin the baths just as soon as he had a suspicion of the existence of typhoid fever, and in this way he had learned that if there was a very decided fall in the body-temperature after the bath, the case was almost certainly not one of typhoid fever. In reply to Dr. Dudley's assertion that the treatment was not eliminative, he would say that the treatment had been found over and over again to increase the uro-toxic coefficient, and also to cause a marked diuresis. If properly carried out it not only did not tend to produce heart-failure, but, on the contrary, was the best remedy to combat heart-failure of which he had knowledge. It was a uniform experience that after each bath the pulse would become decidedly slower and stronger. In country practice, where the Brand method could not be carried out in all its details, a fair substitute might be found in the plan of dashing on the patient some water at a temperature of 60° F.

DR. THOMPSON, in closing, said that he believed that many of the so-called intestinal antiseptics acted beneficially as antifermentatives. If so, they fulfilled an important function, for the prevention of tympanites and distension of the bowels meant less danger of the perforation of typhoid ulcers.

DR. MANGES, in closing the discussion, said that where patients had shown much coldness of the extremities under the tub-bathing, he had found it useful to administer $\frac{1}{400}$ of a grain of nitroglycerin before the bath. Those who had examined the blood before and after these baths, had been struck by the increase of the mononuclear leucocytes after the bath, showing that the treatment was truly eliminative.

DR. MANGES then exhibited the phonendoscope of Bianchi—a kind of microphone intended to take the place of the stethoscope. It consists of a small chamber, closed at the bottom by a diaphram of ferrotype-plate, and having soft rubber ear-tubes, leading from the cover of this box or chamber. It may be used, either by placing the diaphragm directly against the part to be auscultated, or where it is desired to localize the sounds more accurately, a metal stem, three or four inches long, is attached to the diaphragm. This is the best arrangement of the apparatus for use in auscultatory percussion, or where it is desired to perform auscultation through the clothes. Dr. Manges said that the inventor claimed that with this phonendoscope it was possible to detect the muscle-sounds and the normal sounds in the viscera, but this claim he has not been able to substantiate. For auscultation of the heart and lungs, he did not think it possessed much advantage over the stethoscope, but it was certainly very useful in abdominal auscultation.

NEW YORK ACADEMY OF MEDICINE.

General Meeting November 5, 1896.

JOSEPH D. BRYANT, M.D., President.

Surgeon-General GEORGE M. STERNBERG of Washington, D.C., delivered the Wesley M. Carpenter lecture on

THE ETIOLOGY AND CLASSIFICATION OF INFECTIOUS DISEASES.

He defined an infectious disease as one which resulted from the introduction of some disease-producing agent. This agent must be a living organism, either vegetable or animal, in order that the disease may be communicated from one individual to another. Suppuration, he said, was always due to the action of living organisms, except

possibly to the few rare instances in which it resulted from the action of chemical agents. Mechanical irritation was a potent factor, as it often made the tissues susceptible to infection, but it was not in itself capable of producing suppuration. In this connection he recalled some experiments, performed by himself in 1884, with a view of determining the tolerance of the peritoneum to mechanical irritation. The results had surprised him. Fine pulverized, sterilized glass was introduced into the peritoneal cavity of a rabbit, with the result that it only gave rise to a conservative inflammation by which the foreign bodies were encapsulated, and prevented from doing further injury. But if the foreign body carried in with it certain bacteria, the result would be suppuration. In traumatic infection the pathogenic organisms might be derived from an external source, from the surface of the body, or come from within the individual. Auto-infection is the rule in croupous pneumonia and meningitis, and depressing influences of all kinds increase greatly the tendency to infection. It was for this reason that epidemics were observed in connection with famine, and that alcoholic subjects became such an easy prey to pneumonia. In diseases like pneumonia, diphtheria, and cholera for example, there was apparently a local exciting cause, such as a mechanical irritation. Thus, he believed that the influenza-bacillus might exist in the respiratory passages of healthy persons, and not give rise to any symptoms until some depressing factor, as exposure to cold, is introduced. The seasonal prevalence of certain of the infectious diseases was to be explained by the existence at certain times of conditions specially favorable to the growth and multiplication of the specific organism. Again, diseases like measles, scarlet fever, and influenza, spread most rapidly at those seasons of the year when persons are brought into contact in close rooms. It was rather remarkable that although the specific agent of influenza had been discovered as long ago as 1892, but little attention had been paid to this fact, and no precautions were taken to prevent the communication of this disease from one individual to another. In his opinion the bronchial secretions of a person suffering from the influenza were as infectious as were those from an individual having diphtheria.

Some of the specific organisms are capable of being disseminated through the air, but in view of the fact that it had been proved that the cholera-spirillum is destroyed easily by desiccation and sunlight, the view that this disease could be spread by infection of the atmosphere was certainly no longer tenable. On the other hand, it was well known that the malarial parasite could be wafted through the air to a considerable distance, and that the largest number of cases of malaria in a given region would occur close to a marsh, or in such position as to be affected by the winds most often coming from the direction of this swamp. While it was possible that malaria might be due in exceptional instances to the infection of drinking-water, the evidence in support of this theory of its propagation did not seem to be very strong. In the army, the surgeons frequently diagnosticated many cases as malaria, which subsequent *post-mortem* investigation would prove to be in reality cases of very mild typhoid fever. We should be very skeptical about accepting the diagnosis of malaria in any case which fails to exhibit the specific controlling action of quinin. From the fact that malaria is less prevalent in marshy regions when the vegetation of the marsh is completely submerged, he had been led to think that it was not improbable that the malarial plasmodium found its external habitat on the stems and leaves of water-plants, rather than in the water itself. It was quite remarkable that the Washington barracks and Fort Myer, across the river from Washington, D. C., had the largest proportion of cases of malaria of any posts in the United States Army. There was a regular epidemic of malaria every autumn at these posts. At the Washington barracks the water used was from the city water-supply, while that used at Fort Myer was partly from wells and partly from the Potomac.

The occurrence of yellow fever as an epidemic would seem to require the existence of certain sanitary local conditions, and a sufficiently high temperature to allow of the ready development of the specific microörganism. What this organism is, could not be stated definitely, but it appeared to lodge in the alimentary canal, and when discharged multiplied if the soil was favorable for its reproduction. There was no satisfactory evidence that one becomes infected with yellow fever by the ingestion of contaminated water; it was probably rather a disease propagated by breathing an infected atmosphere. It should be remembered that pathogenic material was, in all probability conveyed for limited distances by the feet of such insects as the house-fly and the mosquito.

The two principal etiological factors in the production of infectious diseases are: (1) A susceptible individual; and (2) a specific infectious agent. But another element besides the pathogenic potency of the organism should not be overlooked, *viz.:* the number of these organisms that gain entrance into a susceptible individual. The best classification of infectious diseases at the present time is an etiological one, but it was impossible to make even such a one complete, for diseases were being constantly added to the list. These diseases could, for example, be classified according to the channel of infection, into those due to: (1) Traumatic infection; (2) to infection by contact; (3) infection by the ingesta, and (4) infection through the respiratory tract. Another classification, based on the nature of the infectious agent, would be into two grand divisions, *viz.:* (1) Diseases due to infection by vegetable parasites, and (2) diseases due to infection by animal parasites. There were naturally many subdivisions in such a classification. Of the diseases in the second group, due to protozoa, information was difficult to obtain, as they could not be readily obtained in pure culture, and there were many technical difficulties encountered in this particular field of study. At present, our knowledge does not admit of a proper classification of the eruptive fevers.

H. NEWTON HEINEMAN, M.D., of New York, presented a paper on

THE PHYSICAL AND SCHOTT TREATMENT OF CHRONIC HEART-DISEASE,

based upon personal observation and experience with the method, as carried out at Baden Neuheim. He said that he had become convinced of the superiority of this treatment over the Oertel method. The treatment devised and practised by August Schott consists in the use of resistance-exercises and a system of baths. The waters of these baths contain a large quantity of salts, and also of carbonic-acid gas, and their temperature varies from 80° to 96° F. At first, the duration of a bath should not exceed six or eight minutes, and the higher temperatures should be employed. About one-fourth of the cases showed a distinct change in the size and shape of the heart as a result of the baths, sometimes even of a single bath. This remarkable fact was vouched for by a considerable number of well-known clinical observers. There was no evidence that the ingredients of the bath were absorbed through the skin, but the water was taken into the skin by imbibition, probably to a sufficient depth to influence the nerve-endings—at any rate, the saline baths were found to produce greater tissue-metamorphosis than the other baths. The prescribed exercises should be done slowly and without violence or jerking, and there should be a pause between each movement. When the baths are not used, these exercises should be practised twice daily for from ten to thirty minutes, but when the baths are also employed, only one period of exercising a day should be used. Edema, or moderate chronic renal congestion, forms no obstacle to this treatment, but where there is advanced arterial sclerosis, or excessive debility, it is contraindicated. The bad results are obtained in cases of overstrained heart, or of chronic valvular disease with loss of compensation. The permanency of the results seemed to be beyond question.

Dr. A. Jacobi said that the method appeared to be one of much value, and he would expect it to be especially useful in cases of heart-disease in which the heart-muscle was largely at fault, *e. g.*, in fatty heart. It was dangerous to reduce the fat about the heart rapidly, as it might bring on collapse—in any event, the best result would only be obtained by the avoidance of all violent exercise, and by the frequent repetition of the exercises. He was inclined to doubt the accuracy of the examinations upon which the statement had been made, that a perceptible diminution in the size of a flabby heart would be effected by a single bath. An error had probably crept in from displacement of the diaphragm during the interval between the two examinations, quite possibly as a result of taking some fluid into the stomach.

Dr. William H. Thomson said that he had not as yet employed the baths, but intended soon to add them to the other treatment. He had seen some very gratifying results from the use of gymnastic exercises in cases of senile heart. He would expect the baths to prove very beneficial by their action in improving the cutaneous circulation. A moment's thought would serve to convince one that the impairment of the vast capillary circulation in the integument, such as is observed in chronic Bright's disease, must be a serious load for a weak heart to bear. This peripheral obstruction was largely of reflex origin, and the baths should be able to restore and maintain the normal caliber of these vessels for at least several hours. It had been proved many years ago that even after prolonged immersion in a solution of iodid of potassium, there was no evidence that any of this salt had been absorbed through the skin.

Dr. Jacob Teschner said that in connection with his system of heavy gymnastics for the relief of rotary lateral curvature, his attention had been directed to the effect of exercise on the circulation. He cited several cases, but the following will serve as an illustration: On November 9, 1895, he began these gymnastics in the case of a girl of eleven years, who had a slight aortic murmur, and a pulse of 128 to 140. After the first treatment, the pulse had fallen to 96, and was fuller and of better quality. On November 11th, before beginning the treatment, her pulse was 108; after the exercises, and a rest of half an hour, it was 88. In another week, the pulse was reduced to about 84, and the murmur could no longer be heard. On December 18th, it was noted that the pulse remained constantly between 80 and 84.

Dr. Heineman in closing said that it was worthy of note that after the Schott treatment cardiac stimulants exhibited a power for good far beyond what they had been capable of doing before this treatment. He would especially emphasize the importance of taking plenty of time in securing the desired results.

REVIEWS.

A Text-Book of Materia Medica, Therapeutics and Pharmacology. By George Frank Butler, Ph.G., M.D., Ph.B. Published by W. B. Saunders, Philadelphia.

This is a volume of 858 pages, the text of which is printed in good type on good paper, which is in turn covered by a good binding. Having said this, nearly everything that can be truthfully spoken of the book in commendation has been said, for although it is dedicated "to the medical students of the United States in the hope that it may aid them in attaining a correct knowledge of the nature and action of drugs and the rational treatment of disease," it contains many errors about which there can be no difference of opinion. Of these we shall speak in a moment. The author tells us in his preface that the "original and descriptive properties" of the various drugs under consideration have been adopted almost verbatim from the U. S. Pharmacopœia and the National Dispensatory. For this reason these parts of the work are of course good.

In addition to the actual errors, there are a number of statements which show a very different view of the action of remedies than is generally held by the profession. Thus on page 27 we are told that "a genuine specific is tolerated only by the system in which it antagonizes some disease," and in the next paragraph that "quinin was formerly considered a specific in malaria until the fact was recognized that the drug is analogous to a normal constituent of healthy bile in its action upon plasmodia malariæ." On page 30 we are told that the endermic

method of administering drugs by applying the drug to the sore spot made by a blister, has been found more serviceable than the use of drugs by inunction. On page 32 it is stated that "a single drop of laudanum has caused the death of a child, whereas large doses of belladonna, conium, arsenic, and mercury have been taken with impunity." All mineral acids do not act as astringents, as we are told on page 34, and it is hardly correct to state (p. 36) that cardiac stimulants lengthen the contraction of the cardiac muscle. Again (p. 40), "it is generally thought that vascular stimulants do not dilate blood-vessels nor vascular sedatives contract them." In the article on Chloroform, p. 404, the statement is made that "it affects the kidneys," but we are not told how it affects them, although this is a matter of great clinical importance; and we find no statement of the value of strychnin in the treatment of accidents under chloroform. On page 407 we are told that bromid of ethyl causes "great irritation of the air-passages," which is not true. The statement that the spasms produced by strychnin are "the combined result" of the effect of the drug upon the brain or its vaso-motor center, upon the inhibitory centers of the heart, the respiratory apparatus, and, lastly, upon the reflex-apparatus of the cord, is one of the most remarkable assertions we have ever met. The lower picture on the opposite page is not that of a dog in strychnin tetanus, for its forelegs are flexed and its hind legs are not completely extended. The illustrations entitled "gelsemium-poisoning" do not show the characteristic ptosis and dropping of the jaw which are supposed to be present as the chief dominant symptoms in all cases of poisoning by jasmine. These are the only illustrations in the book devoted to the symptoms of poisoning.

It is wrong to state dogmatically that the solids of the urine are increased by the use of digitalis, for the general belief is to the contrary. The statement that a lethal dose of digitalis may cause tetanic cardiac contraction, "the patient *dying in a few minutes*," is odd. Further, digitalis usually arrests the heart of the higher animals in diastole. On page 546 the statement that "it is wise to give always only such amounts of digitalis as may be requisite to produce the desired effect," is a good general rule of a self-evident character, and the assertion that strophanthus paralyzes the heart in systole is curiously at variance with the usual condition of a paralyzed heart.

Aconite rarely causes vomiting (p. 577), and rarely much pain and nausea. Death from aconite is due to respiratory, not cardiac failure (p. 578). The statements made as to the effect of aconite on the circulation in toxic doses is incorrect. Still more remarkable is the statement that the respiration fails under aconite through paralysis of the peripheral vagi in the lungs. The advice to use emetics to empty the gall-bladder, when this viscus is obstructed by gall-stones, is dangerous. On page 689 we are told to give salines in *plenty* of water, which shows an utter ignorance of the physiological effects of these drugs.

So much for errors. Of the omissions, we find nothing said in favor of or against the use of pilocarpin in eclampsia, and the statement is made that it is useful in humid asthma, when in reality this condition quite strongly contra-indicates it. No reference can be found to gelsemin as a mydriatic, nor of the possibility of accidents under the use of cocain. But thirteen lines are devoted to nitrous-oxid gas, and but one page and a few lines to antipyrin; and finally, for the time and method of administering quinin in malarial fever, we are referred to any standard work on the Practice of Medicine.

MEDICAL AND SURGICAL REPORT OF THE PRESBYTERIAN HOSPITAL IN THE CITY OF NEW YORK. Vol. I. January, 1896. The Knickerbocker Press, pp. 256. Illustrations 36.

AS the title indicates this volume is intended to be the first of a series, and is the result of the very commendable wish on the part of the management of the hospital to advance the knowledge of the nature and treatment of disease. Whether the publication of an annual of this sort is a better way to bring this knowledge before the medical public, than the use of established periodicals would be, is open to serious question, for reports of cases lose their chief value if they are not accessible to the man who looks up the literature on any given subject, in order to draw conclusions from the experience of many men. Be that as it may, the twenty-six articles in this little volume contain much that is instructive in the fields of medicine, surgery, and pathology. The illustrations are good.

BOOKS RECEIVED.

The Annual Reports of the Managers and Officers of the State Hospitals of New Jersey for 1895.

Volume I of the Transactions of the Chicago Pathological Society.

Report of the Pennsylvania State Board of Health, 1894.

Transactions of the American Medico-Psychological Association, 1895.

Philadelphia Hospital Reports, vol. iii.

Proceedings of the Philadelphia County Medical Society, vol. xvi, 1895.

Transactions of the Medical Society of the State of California, vol. xxvi, 1896.

Department of Agriculture—Tenth and Eleventh Annual Reports of the Bureau of Animal Industry, 1893–4.

Proceedings of the Nebraska State Medical Society, 1896.

Year-book of the Department of Agriculture, 1895.

Report of Commissioners of Education, 1892–3, vol. ii, and 1893–4, vol. ii.

Twenty-second Annual Report of St. Luke's Hospital.

Transactions of the American Pediatric Society, Seventh Session, held at the Virginia Hot Springs, May, 1895. Edited by Floyd M. Crandall, M.D. This report consists of thirty-three original papers, together with the president's address and some business details.

Transactions of the American Laryngological Association, Seventeenth Annual Meeting, held in Rochester, N. Y., June, 1895; 233 pages are occupied by the president's address, 24 papers and their discussions.

Transactions of the American Climatological Association, vols. xi and xii, 1895–6. These two volumes contain the records of two very interesting meetings of this important body.

The Report of the Second Annual Meeting of the American Academy of Railway Surgeons. Edited by A. Harvey Reed, M.D., of Columbus, Ohio. The neat volume does great credit to this young association.

Transactions of the State Medical Society of Wisconsin, vol. xxx, 1896. Nearly six hundred pages are filled with a report containing much that is of general interest.

ORIGINAL ARTICLES.

THE OPERATIVE TREATMENT OF RECTAL FISTULA.[1]

BY A. B. COOKE, M.D.,

OF NASHVILLE, TENN.

LECTURER ON DISEASES OF THE RECTUM, UNIVERSITY OF NASHVILLE.

I USE the term rectal fistula instead of the older expression "fistula in ano." This I do advisedly. Only the small group of fistulæ resulting from marginal abscess is properly comprehended under the latter title. In the large majority of cases the internal opening, when one exists, is above the external sphincter, and so, correctly speaking, within the rectum. Rectal fistula, therefore, is the proper title and should always be employed.

Fistula results from abscess. This in a nutshell is the etiology. Other causes which are credited with its production are so rarely in evidence that for all practical purposes they may be disregarded. Abscess is merely the initial stage of a process of which fistula is the effect or sequence. The best kind of treatment is preventive treatment, which means proper treatment of the abscess, *viz.:* early and free incision, perfect drainage, and daily dressings, the great object persistently strived for being to introduce closure of the abscess-cavity from the bottom.

At the very outset of the consideration of the operative treatment of rectal fistula we are confronted by several very important questions: (1) Is there any risk of injury to the general health in curing a fistula? (2) Can a fistula be cured without operation? (3) When pulmonary tuberculosis coexists, is operative treatment indicated or permissible?

In whatever terms couched, the answer to the first question should invariably be in substance that, where no serious complication nor contraindication is present, positive and pronounced benefit to the general health may be confidently expected to follow cure of the fistula.

In answer to the second question, Can a cure be effected without operation? it is possible, but extremely improbable, as well as uncertain. Stimulating injections, the fistulatome, the elastic ligature, and even, in rare instances, the simple passage of a probe may effect a cure. But in such cases the essential condition is that there shall be only one channel, and this condition, especially in long-standing cases, is so seldom encountered that it may be regarded as little less than unique. Open to the same objection is Lange's operation, which otherwise would be as practicable as it is eminently surgical.

A perfectly satisfactory answer to the third question would compel a thorough discussion of the relationship between pulmonary tuberculosis and rectal fistula. In these cases two distinct classes must be recognized, the difference between which is of vast significance. In the first, the fistula is merely a coincident trouble and owes its existence to causes entirely without the pulmonary area—in other words, it is a fistula in a tuberculous subject. In the second, the fistula is secondary to the pulmonary disease and results from it, having its origin in a tubercular abscess in the perirectal tissues, or, in other words, the fistula is itself tuberculous. When the latter condition obtains, unless seen at the very outset, the fistula is practically certain to consist of multiple channels, and the result of operation would be to leave large, open, unhealthy wounds, the healing of which would constitute a very remote probability. And since pulmonary disease is also present, and the patient usually in a greatly enfeebled condition, the administration of an anesthetic would be no inconsiderable risk. Consequently, we may say that in this class of cases operation other than for the purpose of securing drainage would be positively contraindicated. In the former class, however, where the fistula and the pulmonary trouble merely coexist, a different answer may often be given. Here three questions present themselves for consideration: (1) Will the pulmonary disease be aggravated by curing the fistula? (2) Can the patient take an anesthetic with safety? (3) Will the wound heal after operation?

The first question is one which may now be properly disregarded as belonging to the period of surgery, when hemorrhage from internal hemorrhoids was deemed salutary, and when indiscriminate phlebotomy, moxæ, setons, etc., held sway. But the two last questions are of

[1] Read before the Middle Tennessee Medical Association, Pulaski, May 21, 1896.

vital importance. The probability of an anesthetic being safely borne can only be determined by careful physical examination of the lungs, and may be heightened by the employment of chloroform instead of ether. Chloroform is much less irritant to the lungs and, in operations upon the rectum, I have learned to regard it as practically free from danger in addition to possessing decided advantages over ether. Whether or not the wound will heal it is almost impossible to foretell. The general condition of the patient, the manner in which the vital functions are performed, the extent of emaciation, and the amount and violence of the cough must all be considered and duly weighed. If affirmative answers are obtained to both these questions, then operate—one exhausting disease is certainly better than two. The after-treatment will differ materially from that in ordinary cases.

Of whatever variety the fistula may be, whether complete, blind external, or blind internal, the principle of the operation is identical, and its success in any given case will absolutely depend on the methodical observance of four fundamental maxims: (1) Careful and painstaking examination for associate or causative pathological conditions of the rectum. (2) Thorough preparation of the patient. (3) Strict antisepsis, and (4), and probably most important of all, proper after-treatment.

In a typical case of complete fistula the operation is briefly as follows: The patient, having been anesthetized, is brought to the edge of the table and placed in a lithotomy-position, the legs being supported by a Clover's crutch. A strong, grooved director is then passed through the fistulous tract, the end received upon a finger of the other hand introduced into the bowel, and, if possible, made to emerge through the anus. With a strong, curved bistoury, or pair of scissors, the bridge of tissue overlying the director is then completely divided. Now the operation is only begun. Every sinus and diverticulum is to be sought out and divided. Then with a curette or sharp spoon the diseased lining membrane of each sinus is to be entirely scraped away, and all thin and overlapping edges trimmed off. The surgeon who hesitates to sacrifice tissue in this operation, like him who aims for cosmetic effect in the removal of a carcinomatous breast, courts failure and disappointment. The wound left by an operation properly performed, in some cases, is formidable to behold. It is occasionally even necessary to remove the larger part of a buttock. But under strict antisepsis large wounds are not to be feared. Even in the worst cases healing and recovery are often astonishingly rapid.

Where the fistula is of the horse-shoe variety, *i. e.*, with the external and internal openings on opposite sides of the rectum, or with two or more cutaneous openings, and only one mucous, some modification of the operative procedure will be required. In these cases it is better to follow up the different channels by dissection from without, in order to obviate the danger of dividing the sphincter in more than one place. This is never necessary, for however many external openings there may be, it is a rare exception for more than one internal opening to be found.

In the variety known as anal, or marginal fistula, the operation is the same as given for the complete variety, only much simpler. After division of the sinus the operation is completed by merely drawing the knife through its base so as to sever a portion of the fibers of the sphincter and set the parts at rest. In other words, first convert the fistula into a fissure and then cure it by the Boyer method. General anesthesia is not always essential for this manipulation.

Whatever the variety of fistula, an important point, and one on which the success of the operation will largely depend, is to remember that the mucous membrane is frequently undermined for considerable distance around the internal opening, a submucous tract sometimes running up the bowel for an inch or more. It is always necessary to trim away this overhanging tissue and to divide the submucous channel to its farthest point.

Now we come to the questions of dressing and after-treatment. These are the crucial features. Hemorrhage from every source having been perfectly controlled, the raw surfaces irrigated and dried, and an anodyne suppository inserted, if deemed advisable, the first dressing should consist of iodoform-gauze placed lightly—not packed—in the wound until it is filled in every part and from the bottom. Over this bichlorid-gauze is placed and covered by a generous pad of absorbent cotton, and the whole retained in place by a T-bandage firmly applied. Unless indicated by the amount of exudation or discomfort of the patient, the dressings need not be changed until the second or third day, at which time the bowels should be moved. Over this the surgeon or a competent assistant should exercise personal supervision. It is best accomplished by administering a laxative twelve hours in advance, and preceding the stool by an enema of tepid water or, better, the injection of half a pint of pure olive-oil. The parts are then to be thoroughly

cleansed, the wound well irrigated with an antiseptic solution and fresh dressings applied in the same manner as before. This is to be repeated after each stool. The patient should be kept on a light but nourishing diet, and any tendency to diarrhea met by an occasional dose of bismuth.

Nothing is to be accomplished by keeping the patient in bed for a prolonged period. Especially to the tuberculous subject exercise, air, and sunshine are of the first importance, and provision should be made accordingly. After the second or third dressing in ordinary cases, if everything goes well, the patient may be directed to report at the office for further treatment.

One precaution which should be observed at every dressing is to pass a probe or the finger to the bottom of the wound, so as to break up any adhesions which the gauze may have failed to prevent. The principle upon which hope of success is to be placed is closure of the wound throughout its whole extent from the bottom.

The wounds necessitated in this operation are occasionally so large that their healing requires months; but with a careful observance of antiseptic precautions I have seen even the largest carried to a perfect result without the appearance of a single trace of suppuration.

The dangers of the operation are practically limited to two, *viz.*, hemorrhage and incontinence of feces. The former is almost exclusively a primary danger arising at the time of operation, chiefly in those cases where the internal opening is far up the bowel and the tract passes through the pelvic diaphragm and the so-called superior pelvi-rectal space, and in patients the subjects of hemophilia. Modern hemostatics have minimized this danger, and only the timid and unskilful hesitate to incur it. When ligation of the bleeding points is impossible, the free use of ferrous sulphate and iodoform, equal parts, or the former alone, will nearly always prove successful. If other means fail, the resource is still left of plugging the rectum. When this expedient is resorted to, provision for the escape of flatus should always be made, else great discomfort to the patient is sure to ensue.

The other danger, incontinence of feces, is properly speaking a sequence. It likewise arises most frequently in those cases in which the internal opening is above the pelvic diaphragm, and always follows division of the sphincter at more than one point. The most satisfactory methods of treating this condition are, according to the case, application of the actual cautery, and approximation of the severed ends of the sphincter by dissection and suture.

A brief summary of the more important points made, together with a few general remembrances, may not be out of place:

1. A careful physical examination of the lungs as well as of the entire rectum to be made in every case.

2. Pulmonary tuberculosis not necessarily a contraindication.

3. Do not put down knife until certain that every sinus has been divided.

4. Remove *all* diseased tissue. Large wounds not to be feared.

5. Caution: The sphincter to be divided only once and at right angles.

6. Special attention to the mucous opening.

7. Invasion of the perineum to be avoided, especially in females.

8. Systematic antisepsis necessary if good results desired.

9. Care and patience in the after-treatment. Dressings not to be left to the family or nurse.

10. In the after-treatment two warnings to be heeded: Complaints of unusual pain by the patient and increase of the discharge. Either of these may mean the formation of another abscess.

11. Hemorrhage and incontinence of feces the chief dangers. Both amenable to treatment and should not deter from the operation.

I should feel recreant to duty did I close without a plea for careful, thorough, painstaking examination in every case of rectal disease. The subject of fistula is an important one, and far more frequent than is generally supposed, being limited to no age, class, nor condition of life. Yet, in common with every other disease of this portion of the body, it is usually termed "piles" by its possessor, and as such prescribed for by the physician consulted without an examination even being requested.

THE PROPER MANAGEMENT OF APPENDICITIS.

By J. W. HICKMAN, M. D.,
of Tacoma, Washington.

The medical world has not yet arrived at a uniform method of treating appendicitis. It would seem, when taking into account the voluminous literature upon this subject and the great mass of facts that have been collected, that the wide differences of opinion in this direction should not obtain.

There are able men who would operate on every case at the earliest possible moment after making

sure of the diagnosis. Again, there are among our best surgeons those who would wait until there has been pus-formation, or at least an appreciable tumor. There are equally good surgeons who hold a middle ground and call it conservative. The position of the latter would be impregnable were they able to diagnosticate the catarrhal from the suppurative form of the ailment. The one does not always require operation, the other does.

It cannot be denied that operation in every case as soon as the diagnosis is satisfactorily made will, in skilled hands, give results almost, if not entirely, free from a death-rate. Nor can it be denied, either, that by this rule some cases will be operated upon that would get well and stay well without operation. The central query here is this: What percentage of catarrhal appendicitis will be followed by a recurrence, and what percentage of recurrent appendicitis will forever remain free from pus-formation? I have seen no statistics that will satisfactorily answer these questions. I have recorded in my note-book details of a case that occurred five years ago. The attack was a typical one; the symptoms were all severe; the patient was confined to bed for ten days, and during the week following there was a readily perceptible tumor, tender to moderate pressure. This case was preceded by constipation, and it is recorded that the cause "was acute indigestion." There was no recurrence till one year ago, and then a very light attack, which disappeared after the exhibition of a saline cathartic. Since then the patient has been well.

I have a little patient of twelve years who has an attack of appendicitis whenever she becomes even slightly constipated. The temperature rises to 100° F.; the pulse ranges from 100 to 120; colicky pains appear in the abdomen, with tenderness at the McBurney point and rigidity of the right rectus muscle; sometimes there is a little vomiting. This whole condition clears up as soon as the bowels have been thoroughly acted upon by sulphate of magnesia. She has had seven attacks within the last year; they do not increase in severity, and the condition is just as easily relieved as the first one was. I have seen several cases in which there has been no recurrence for one, two, and three years. Whether it is possible to have one attack and never have a recurrence, is a point I am not sure of. I do, however, feel sure that a recurrence is the rule; and I also feel sure that, sooner or later, an operation will be demanded in most cases, either because life is in jeopardy or because the patient will get tired of being confined to bed for several days at varying intervals. I have also observed that an operation is usually more difficult on account of adhesions in patients who have had several recurrent attacks of catarrhal appendicitis; especially have I found this to be true when the appendix has been located posteriorly, pointing backward and upward. I have often wished in such cases that I had operated at the beginning of previous attacks.

Just as soon as we are able to differentiate those cases in which there will never be an abscess, and in which there will not be adhesions that will cripple portions of the bowel and thus interfere with its function, there will be a better reason to condemn those who operate in every case they see. At present it is not possible to do this. A more carefully conducted observation of all cases of appendicitis and more accurately kept records will contribute much to this end. All cases of appendicitis are not alike either in their morbid anatomy or their subjective and objective symptoms. It is, therefore, desirable to study each case with as judicial a mind as possible. This course and less of dogmatic assertion will lead medical men to more rational conclusions.

It is certain that an operation will cure appendicitis and forever prevent a recurrence. Now, is it equally certain that therapeutic measures other than this can accomplish as much? Operation furnishes the only possible means of saving life in a suppurative case. I must make a single exception that will include but a very small percentage of cases, namely: where adhesions are strong and the pus finds its exit either at the surface of the body directly or *via* one of the abdominal viscera. Will any medical man tell us how to make a differential diagnosis between the catarrhal and suppurative form of the disease before an abscess has actually occurred? It will not be enough to reply that the suppurative form may be recognized by the severity of symptoms either subjective or objective. Such a test is not a guide at the bedside. No one, so far as I know, has yet claimed to be able to separate the two prior to pus-formation. The surgeon who operates indiscriminately on all cases will operate on a certain percentage of cases where no immediate necessity for operation exists. Suppose he does; if he be competent to operate at all, what risks are run by his patient? But one; namely: ventral hernia in the future. By a short incision, by a careful approximation of divided surfaces, and an accurately fitting bandage for a year, the

percentage of hernia will be small, much smaller indeed than the death-rate resulting from an indiscriminate dependence upon purgatives and expectancy.

A few years ago I saw a case of appendicitis in a patient with advanced pulmonary tuberculosis. Owing to the latter condition no operation was advised. The symptoms were not more severe than I have observed scores of times in catarrhal cases, nor, so far as I could observe, were they different. A small tumor could be felt. At five P.M. of the fifth day he was suddenly seized with terrific pain shooting through the abdomen in every direction, and at midnight he was dead. The necropsy revealed the usual ragged hole at the base of the appendix, which had been enclosed by some weak adhesions, and the peritoneal cavity was full of pus.

My note-book contains records of another case interesting in this connection, and particularly interesting in another connection, *viz.:* to illustrate a point made above, that all cases are not marked by the same symptoms. This patient was attending to his business as usual when, with as abrupt suddenness as ever marks the entering of a duct by a calculus, he was stricken with abdominal pain of a most violent character. The pulse was rapid; temperature at first scarcely elevated. There was frequent vomiting; tenderness over the abdomen, not more marked in one place than another; marked tympany; in short, the case was, so far as could be made out, one of peritonitis. Twelve hours later the patient was in collapse, and about thirty hours from the beginning he was dead. Again the necropsy revealed the small, jagged opening at the base of the appendix, and the belly full of pus, but this time no trace of an adhesion anywhere.

The first case, as I have said, was not seemingly very severe, in fact, was just such a case as many an able practitioner would have treated expectantly. Though it was a suppurative case it wore no peculiar livery that would separate it from a catarrhal case of the same severity, so far as the physicians in attendance were able to observe; yet it must be admitted that no remedial resource save an operation would avail anything in such a case. In the latter case, had the belly been opened immediately, it is possible, though I admit not very probable, the patient's life might have been saved.

Since beginning this paper I have operated on a case, the main points of which I shall mention very briefly. The patient, a telegraph operator, had been suffering for ten days when I first saw him, and had during most of this time attended to his work. At the time of my visit I found a tumor at the usual site, temperature was 100°, pulse 90, and there was not much pain, nor was the tenderness excessive. I operated at the earliest possible moment, and found an appendix covered in by the omentum, thickened to the extent of three-quarters of an inch, just as a handkerchief might be made to cover in a finger. Upon separating the omentum from the appendix, I found three or four drams of stinking pus and two ragged holes in the appendix. A large piece of omentum had to be removed. There were no other adhesions than between the appendix proper and the overlying omentum. Externally to the base of the appendix there was seen a gangrenous patch of cecal wall about the size of a dime. The case is doing well. The operation was an absolute necessity, and was very difficult; had it been done early it would have been very simple. On account of the pus it was necessary to leave most of the incision open, a grave disadvantage, that would have been obviated a week earlier. There was absolutely nothing in this case prior to operation that I have not seen duplicated in simple catarrhal appendicitis; yet here was pus and here was also a patch of gangrenous cecal wall, not covered by any adhesion, that would in a few hours have permitted the contents of the gut to have escaped into the peritoneal cavity.

The question of the proper management of appendicitis is capable of any amount of argument, but I am entirely convinced that the disease is purely a surgical one, that the only safe treatment is operation. Other therapeutic measures will avail in perhaps a majority of cases, at least in the first attack, or possibly in the first few attacks. I know, however, that any other means of treatment will be marked by a mortality-rate, and this must be true until we are able to separate catarrhal from suppurative cases. This I repeat cannot be done at present. Then why not operate at once in all cases? Such a course, in properly qualified hands, is as nearly absolutely safe as any operation can be. Suppose some cases are operated on that would have gotten over the attack without operation; better this than to run so grave risk as we must encounter when we wait.

Infected Cuba.—A recent report to Surgeon-General Wyman tells of an increase of both smallpox and yellow fever in Havana. The latter disease is chiefly confined to the Spanish troops, while the natives furnish most of the smallpox-cases.

ERUPTIONS FROM MERCURY.[1]

BY DOUGLAS W. MONTGOMERY, M.D.,
OF SAN FRANCISCO;
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA; CONSULTING PHYSICIAN FOR DISEASES OF THE SKIN AND FOR PATHOLOGY, GERMAN HOSPITAL.

MERCURY and its preparations are powerful in altering physiological action, and in controlling disease, and in some susceptible people this power may produce either dangerous or disagreeable effects. It causes, for instance, a variety of rashes of the skin, most frequently an erythematous or scarlatinoid eruption, of which the following are examples:

On December 3, 1893, a healthy, bright-complexioned, dark-haired man, twenty-six years of age, consulted me for a nummular psoriasis of the trunk and extremities that had appeared for the first time a few days before. A salve was ordered consisting of equal parts of white-precipitate and oxid-of-zinc ointments to be rubbed into the patches. The diseased areas did not implicate much of the skin, and no trouble from absorption of the drug was expected. Furthermore the preparation was not a strong one. The unguentum hydrargyri ammoniati is a ten-per-cent. ointment, and it was reduced by the addition of oxid-of-zinc ointment to five per cent. Four days after prescribing for the patient, I was called and found him suffering from a bright-red, itching, and burning rash, that was most marked at the flexures of the joints. As the patient suspected he might be suffering from syphilis it became important to determine the true nature of the eruption. It was clearly not a syphilitic roseola, which is spotted, whereas this was diffuse, and furthermore the syphilitic rash is without subjective symptoms, while this was extremely itchy and burning. On stopping the use of this ointment the rash quickly disappeared. The violent reaction of the skin had, however, a favorable effect on the psoriasis, which also faded away, and had not reappeared when the patient was last seen by me two and a half years afterward.

Although the eruption was ascribed to the mercury, yet there was a possibility that it might have been due to other causes, for instance to the fat of the ointment being rancid, as there are fatty acids in rancid fat that are very irritating to sensitive skins. Neisser[2] says that the so-called mercurial eczemas from the application of blue ointment are caused by inferior ointments that contain turpentine, fatty acids, nitro-benzol, etc. He does not, however, deny[1] the existence of true mercurial exanthems.

A subsequent experience with the same patient, however, showed that the mercury was really the offending substance. On November 16, 1895, he came to me with a pimple on the frenum of the penis, and a small shallow ulcer with a dirty, yellow floor, in the sulcus. These lesions had appeared a day or two after exposure. Not thinking of his susceptibility to mercury, black wash was prescribed, and by the next day he had a dermatitis mercurialis of the glans (balanitis mercurialis), with considerable edema of the prepuce. The black wash was suppressed, and he was ordered a powder of subgallate of bismuth, under which both the venereal and mercurial symptoms quickly disappeared. As is well known, black wash is for most people a very mild preparation, made by adding one dram of calomel to a pint of lime-water (1–128).

Calomel is usually a very mild preparation, causing no irritation either to the skin or to the mucous membranes, but not long since I had an experience illustrating its power of causing a disagreeable eruption. A man, forty-five years of age, who was confined to his bed on account of an operation for a large sarcoma of the thigh, but who otherwise enjoyed good health, got an uncomfortable itchiness of the anus and scrotum, which was probably caused by indigestion and constipation, brought on by confinement in bed. As the mercurial preparations are among the most successful antipruritics, and calomel-ointment is particularly useful in pruritus ani, a dram of calomel rubbed up in an ounce of simple ointment was ordered applied to the anus, perineum, and scrotum. In a couple of days the skin of the genitals and crotch was scarlet and swollen, with marked edema of the prepuce. But on discontinuing the calomel-salve, and applying an oxid-of-zinc ointment, the erythema quickly subsided. In this case there was a superficial dermatitis around the field of operation on the thigh, and the inflammation of the genitals might easily have been mistaken for an erysipeloid extension of the process. Gaucher,[3] in mentioning the rarity of calomel causing an eruption of the skin, relates a case where a single application of calomel-ointment caused an erythematous and eczematiform eruption implicating nearly the half of the body. After this rash disappeared, the patient took two

[1] Read before the California State Medical Society, Los Angeles, April 24, 1896.

[2] "Leçons sur les maladies de la Peau," par E. Gaucher, 1895, p. 113.

pills containing a centigram of sublimate each, and the day following he had a generalized desquamative scarlatiniform erythema, accompanied by a vesicular eruption simulating eczema.

But in attributing a mercurial dermatitis to the action of calomel, when applied to the genitals, one must be on the alert for at least two sources of error; in the first place, that the irritation may not be due to the mercury at all, but, as suggested in the relation of the preceding case, to the action of rancid fat in the ointment-base; and in the second place, that the patient may be taking potassium iodid, which, being voided in the urine, comes in contact with the calomel, and forms the biniodid of mercury, a very much more irritating salt. In 1890, Cordier[1] drew attention to the fact that a severe balanitis may occur from the potassium iodid in the urine coming in contact with calomel dusted on the glans. For this to take place, however, a long foreskin seems to be necessary, so that a very considerable quantity of urine may be sucked up under the prepuce by capillary attraction. It would be quite unlikely that dribbling urine containing potassium iodid coming in contact with calomel-ointment would make enough biniodid of mercury to irritate the skin of an ordinary individual. It is as well, however, to bear this contingency in mind in any case like the above, where such a mild preparation as calomel irritates[2] the skin. This patient was not taking potassium iodid during the time the calomel-ointment was being applied to the genitals.

In this same patient the sarcoma recurred in a few weeks, and a second operation was undertaken for its removal. Without thinking of his susceptibility to mercury, a sublimate gauze-dressing was applied to the wound. On the second day the skin was bright-red, tense, shining, and excruciatingly itchy, and the affection might easily again have been mistaken for erysipelas. The dermatitis quickly subsided on changing the dressing.

In both these cases, therefore, a rash was caused by an ointment containing a mercurial preparation, and, as if to show conclusively that it was the mercury and nothing else that caused the mischief, the other mercurial preparations that were not applied as ointments also caused an erythema. Both patients were very sensitive to mercury, but fortunately they got well promptly on the withdrawal of the drug. This does not always occur, however, as the rash may continue for a long time after all contact with mercurial preparations has ceased.

Another fortunate circumstance was the localization of the erythema to those parts where the mercury has been applied, as a single application to a limited portion of the skin has been known to cause a widespread rash, as in a case reported by Dr. Alexander,[1] where a ten-per-cent. white-precipitate salve applied once to the eyelids caused a universal eczema.

[1] Sur une nouvelle variété de balanite, *Lyon Médical*, No. 1, 1890. Abstract in the *Annales de Dermatologie et de Syphiligraphie*, 1890, p. 442.

[2] Oculists have long been aware of the danger of dusting calomel in the eyes of patients taking potassium iodid internally, as the potassium iodid in the tears, coming in contact with the calomel, may form the biniodid of mercury, of which a very small quantity is irritating enough to cause a severe conjunctivitis.

SERUM-THERAPY AND PROTECTIVE INOCULATION.[3]

BY JOHN RUHRÄH, M.D.,
OF BALTIMORE, MD.;
RESIDENT PHYSICIAN, BALTIMORE CITY HOSPITAL; DEMONSTRATOR OF BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

(Concluded.)

Syphilis.—In syphilis we see a natural immunity under several different conditions: in the tertiary stage of the disease for primary and secondary symptoms; in children of a syphilitic mother (Profeto's immunity); and in the mother giving birth to a syphilitic child (Colle's immunity). The experiments in producing curative effects by the use of blood-serum are embodied in a number of reports. Richet and Hericourt were the first to try it, and in 1891 treated several cases with serum from a dog which had been injected with the blood of a syphilitic patient. The two cases first experimented upon are of historic interest. The first patient, a woman, who had contracted syphilis twenty years before, presented symptoms of a tabetic nature, and these were cured by three injections of 2 c. c. of serum within a week. The second patient, a young woman, with syphilis of eighteen months' standing, showing a great deal of ulcerating surface, was greatly benefited after seven injections, the ulcerating surfaces decreasing in size by four-fifths. Tommasili, Giuseppe Mazza, Kallmann, and others used the serum from the blood of animals naturally resistant to syphilis, such as dogs, sheep, calves, lambs, and rabbits. This serum, while apparently causing improvement at first, was followed subsequently by a return of the acute symptoms, and the disease ran its course uninfluenced.

Pellizzari was the first to apply to syphilis the procedure used in other infectious diseases, *viz.*: that of using blood-serum from animals having an

[1] *Arch. f. Dermatologie und Syphilis*, 1884, p. 105.

[3] Prize-essay for 1896 of the Alumni Association of the College of Physicians and Surgeons, Baltimore.

acquired immunity. He injected a serum from a tertiary-stage syphilitic into patients suffering from an earlier stage of the disease. The results were not very successful, evidently due to the weakness of the serum. The cases ran their usual course, although decreased in duration and intensity. Gilbert and Fournier of Paris treated a number of cases with serum prepared from she goats and dogs. These animals were injected with the blood of syphilitics presenting fully developed secondary symptoms. Ten injections were given to them in fifty days, using 180 grm. of blood. Other goats were inoculated with nine chancres in two months, and another dog with chancres and papules, and also given blood-injections. The serum from the animals was apparently about the same. Seventeen cases were treated in all with varying results. In some cases little or no effect was noted; in others there were improvement in general conditions, recovery of strength, and abatement of symptoms.

Neumann of Vienna reports a number of cases treated with lamb's blood, and with the blood of a tertiary syphilitic. Results were in the main unsatisfactory, some improvement being noted, but it was not permanent. Researches in the use of the blood-serum of tertiary syphilitics by Vieviorovsky of St. Petersburg confirm Pellizzari and Gilbert's reports. Five cases were treated.

The application of serum-therapy to syphilis meets with practical difficulties, among which is the absence of a knowledge of the specific cause of the disease. In this connection, however, it has not the practical importance that it has in other diseases, for we already possess very efficient means of treatment, but there are cases that resist mercurials and iodids and in these it would be particularly valuable. In a disease like syphilis, with its manifold late manifestations, a generation or two must live and die to determine absolutely the value of any new treatment.

Typhoid Fever.—In this disease some very interesting work has been done; beginning with the researches of Chantemesse and Widal in 1892. These observers found, as early as 1888, that susceptible animals could be rendered immune by inoculating them with cultures of the typhoid organisms which had been rendered sterile by heat. These showed immunity from inoculations with the typhoid bacillus, but not from its toxin. This toxin was first described by Pfeiffer in 1894. He found that it was associated with the body of the bacillus, and that it was not found in cultures sterilized by filtration. The toxin is not destroyed at the temperature, 54° C., which kills the organism.

Neisser in 1893 found that mice injected with the blood-serum of convalescent typhoid patients resisted three or four times the usual toxic dose of cultures of the organism. Stern, in 1894, found that the blood of individuals who have previously had typhoid produced immunity; also that the blood from fatal cases had the same effect. In the fatal cases the blood was taken from the body shortly after death. He also found that in a series of persons who had not had the disease, the blood in some cases caused resistance to the organisms, although larger doses were required. Stern suggests that in these cases the patients had suffered from an unrecognized attack of typhoid. Another interesting point was elicited in 1894 by Cæseris, Demel, and Orlando. They found that animals rendered immune from the coli bacillus of Escherich were also immune from typhoid fever, and *vice versa*. Peiper, before the German Congress of Internal Medicine, August, 1895, reported that he had immunized sheep against typhoid by repeated injections of cultures of the typhoid bacillus sterilized at 55–60° C., which, of course, did not destroy the toxin. The serum from these animals, when injected into guinea-pigs, protected them from several times the toxic dose of the bacillus of typhoid fever, and cured guinea-pigs inoculated with a fatal dose, even when administered some three or four days after injection.

The application of an antityphoid serum to the human being was made by F. Klemperer and E. Levy in the wards of Dr. Naunyn of Strasburg. The serum was obtained from dogs protected by inoculations of cultures of medium virulence. Five patients in the first week of the disease were inoculated with 20 c. c. of serum on three successive days. The injections were well borne, and produced neither albuminuria nor urticaria. The disease ran a shorter course than usual in each of these cases. The fever at once showed marked morning remissions, and ceased entirely toward the close of the second week, or at the beginning of the third. One case relapsed after a week. There is such a marked difference in the various cases of typhoid that it is impossible to form anything like a definite idea of the value of this treatment. The small number of cases treated could easily make the results appear as coincidences.

Another method of treatment was tried by Fraenkel and Manchot in 1893. They treated fifty-seven cases of typoid with sterilized cultures of the bacillus grown in thymus-bouillon. The course of the fever was considerably modified,

apyrexia occurring earlier, and the morning remissions being more marked. The same treatment, using instead the *Bacillus pyocyaneus*, was tried by Rumpf in 1893, and Kraus and Buswell in 1894. The results were unsatisfactory. Leaving out the five cases of Klemperer and Levy, nothing has been done in the serum-treatment of this disease of any practical importance. The fact that the disease runs a definite course and is followed by a slight period of immunity, makes it seem probable that further developments may give more satisfactory results.

Asiatic Cholera.—Among the diseases that have come in for their share of research-work in protective inoculation is Asiatic cholera. Many curious and interesting facts have been elicited concerning this disease and the toxin of the spirillum of Koch, or what is ordinarily spoken of as the comma bacillus. Several toxic substances have been isolated by Brieger and others, but the principal interest attaches itself to the protective inoculations of Ferran, and later of Haffkine, and to the serum-treatment of Ransom, the last named not yet tried upon man.

The method of Ferran, which was extensively used in Spain during the epidemic of 1885, consisted in the injection of 1 c. c. of a pure culture of the culture in bouillon into each arm of the person to be protected. The official reports were collected some time after its use, and there has been much written and said concerning the efficacy of the treatment. According to the official reports, the death-rate was about 43 per cent. in unprotected individuals, and 25 per cent. in protected individuals attacked. A much less number of the injected had the disease, than of those unprotected.

Shakespeare, who was sent to Spain by the United States Government, reporting upon the method says: "It would seem from analysis of official statistics that the method of anticholeric inoculation after the method of Ferran, besides giving immunity from attack and death by cholera, furnishes a means of bringing an epidemic to an end."

Haffkine of the Pasteur Institute in 1893 published his method of protective inoculation for cholera. This method, first tried upon animals, next upon himself and other individuals, and subsequently upon persons in India, shows it to be without danger. It consists in acclimatizing the system as it were, first to weak cholera-poison, and then to stronger poisons, or, as Haffkine calls it, the poison from "exalted" cultures. This develops a high degree of resistance in animals and also in man. The aim is to establish a resistance sufficient to withstand the absorption of the cholera-poison from the intestinal tract, should infection take place. The vaccinations are usually done upon the arm and cause only slight malaise and some edema and tenderness about the puncture. The vaccines consist of attenuated and exalted cholera-cultures, and may be either of living bacteria or an emulsion of cholera bacilli that have been killed by dilute carbolic acid. The living vaccines are more powerful and are difficult to keep and transport; the carbolized vaccine is not so powerful but is less liable to prove a source of infection, and it also keeps well and may be easily carried about.

The attenuated cultures are obtained by growing the organism in a medium, aerated at 39° C. for several days. The exalted cultures, which are very virulent, are grown in the peritoneal fluid in the peritoneal cavities of live guinea-pigs. As soon as an animal dies, the peritoneal fluid is transferred to the peritoneal cavity of another under the strictest aseptic precautions. This is continued until the cholera-spirillum has obtained its maximum exaltation, determined when the time between inoculation and death is no longer shortened. Generally from twenty to thirty guinea-pigs are used before this comes about. The bacilli-laden fluid is then inoculated into an agar-tube of standard size, and a smooth, even surface-culture obtained by growing it for twenty-four hours in a thermostat. Two or three cubic centimeters of broth are then put in the tube and the culture thoroughly mixed with it. It is then pipetted off and broth (bouillon) added to make 8 c. c. The carbolized vaccines are similarly prepared, using instead five-per-cent. carbolic acid. Only 6 c. c. are made from a tube, in order to compensate for the loss of strength on adding the acid. The attenuated vaccines are prepared in the same way. One cubic centimeter is a dose, and from three to five days elapse between the vaccinations.

The method was tested by Haffkine in India from April, 1893, to July, 1895, and he summarized his results before the Royal College of Physicians and Surgeons as follows: "In all those instances where cholera has had a large number of victims, that is to say, where it had spread sufficiently to make it probable that the whole population inoculated and uninoculated were equally exposed to infection, in all these places the results appeared invariably favorable to inoculation. After an epidemic actually breaks out, it tends to reduce the mortality even during

the time which is claimed for producing the full effect of the operation."

Koch believes that, from Haffkine's reports, the value of the inoculations has been determined. Haffkine intends, however, to make further studies in this line, and also to test the power of antitoxic serum obtained from immunized animals. Pfeiffer of Berlin has prepared a quantity of an antitoxic serum that is very active in animals, and that Haffkine intends to use in his first experiments.

The application of serum-therapy to cholera is embodied in a few scattered reports by Pawlowsky, Buchstab, Federoff, and others. The results show that dogs and guinea-pigs may be rendered immune by injection of blood-serum from animals that have been immunized by means of sterilized cultures. Freymouth of Danzig reported three cases treated by inoculations of serum from individuals who had recently recovered from the disease. One died. Of the others one received 80 c. c., the other 20 c. c. of serum.

By far the most important results have been obtained by Ransom, who reported his experiments in July, 1895. He obtained a toxin from cholera-cultures by a method that he does not describe—a solid, having the same properties as the vibrio and its cultures. With small doses of this toxin he immunized guinea-pigs, sheep, and goats, and obtained a blood-serum possessing antitoxic properties against the cholera-poison and the living cholera-vibrio. As yet the serum has not been tried upon man, but from a theoretical standpoint it promises better success than the methods of other investigators.

La Grippe.—The practical application of serum-therapy to the treatment of influenza, or la grippe, as it is called, has not yet been made, but, in view of the experiments of Bruschettini on rabbits, it seems highly probable that something may be done in this line. In 1893, this observer published the results of his experiments, which, in brief, are as follows: He vaccinated rabbits with a filtered blood-culture of the bacillus of Pfeiffer, which is now established as the cause of the disease. The blood of rabbits so inoculated contained an antitoxin that, inoculated into rabbits infected with the grippe-organism, exerted a most marked curative action. It conferred immunity on rabbits when used in the proportion of 1–42,000 of the body-weight.

Bubonic Plague.—Another recent discovery in immunity has been made by Yersin, Calamette, and Borrel of the Pasteur Institute, working under Roux's direction. They have succeeded in showing the possibility of immunizing animals from bubonic plague, and in curing those suffering from the disease. Immunity was conferred on rabbits, guinea-pigs, and mice by means of injections of large quantities of the cocco-bacillus of Yersin, which had been heated for an hour at 58° C. The filtered cultures had no effect on the animals. Serum from these animals conferred immunity on other animals. A horse, immunized by a similar method, gave a serum that produced immunity in animals. It is well to note that no other curative serum, antidiphtheritic, anti-erysipelatous, antitetanic, or antivenomous produces immunity or cure in the plague.

Typhus Fever.—In passing rapidly over the various diseases in which the serums have been used, one should not leave out typhus fever, as Legrain, according to the reports of Shaefer, used the blood-serum from patients who had previously suffered from the disease, with alleged good results. This was during an epidemic in Algeria.

Yellow Fever.—Much more interesting to Americans is the plague of the Southern countries—yellow fever. Sternberg, in his book "Immunity and Serum-therapy," in the chapter devoted to this subject, cites some attempts at producing immunity in that disease that are amusing, if not of scientific value. Among them is the method of Humboldt, who attempted to produce immunity by inoculating animals with the putrefying livers of sheep which had been bitten by a certain species of serpents. The recent so-called mosquito-inoculations are interesting, though not successful. These consisted in allowing a mosquito that had fed upon a yellow-fever patient, to sting a person desiring to be inoculated. The inoculation recommended by Freire of Rio Janeiro deserves mention on account of the prominence given to the method. This consisted in vaccination with attenuated cultures of a micrococcus, that Freire thought to be the cause of the disease. It is hardly necessary to add that this micrococcus is not admitted to that important *rôle* by competent observers, and that the vaccinations proved fruitless.

Pneumonia.—A few years ago the medical world was aroused by the experiments of G. and F. Klemperer concerning the toxin and antitoxin of the *Diplococcus lanceolatus capsulatus* of Fraenkel, the specific microörganism of lobar pneumonia. They succeeded in isolating a toxalbumin from bouillon-cultures by precipitating it with alcohol. By using filtered cultures, they immunized rabbits. They claimed that there is an antitoxin produced in the blood of the immunized animal that renders the toxin innocuous.

Issaeff differs with them in this respect, as he claims that rabbits are rendered immune from inoculations with the diplococcus, but not from injections of the toxalbumin. However, the blood-serum of these immunized animals, when injected into other animals, produces immunity from inoculation and, furthermore, if the animal is already infected, it exerts a marked curative effect. Encouraged by these successes, the serum was tried upon six cases of pneumonia in Leyden's clinic in Dresden. About 6 c. c. was injected under the skin of each patient; all recovered. In all the cases there was an immediate fall of temperature to normal; in two cases it remained normal, and in two others it rose again in six hours. Emmerich claims that a degree of immunity higher than that produced by the Klemperers can be brought about, and he expresses great hopes for the future of serum-therapeutics in pneumonia. Certainly, a much higher degree of perfection in methods, and many more convincing experiments must be made before it can be applied to the treatment of the disease in general practice.

Smallpox.— The phenomena and history of smallpox are too well known to need more than passing notice. We know but little more of the disease than Jenner did. The cowpox is rather to be regarded as a modified form of smallpox in the bovine than a special disease, and this is especially true when viewed in the light of recent revelations in the immunity produced in other diseases. Sternberg, and subsequently Kinyon, showed that the blood-serum from an immune calf prevented vaccination from "taking" if the vaccine-points were immersed in it. This was found to be true of both bovine and humanized vaccine-virus. Sternberg, and later Kramer, Boice, and Landmann showed that injections of blood-serum of immunized calves, or of patients recently recovered from smallpox, did not prevent the formation of the vesicle. Béclère, in December, 1895, before the Paris Academy of Medicine, stated that he found by experiment that the blood-serum of a heifer, if taken after the active stage of vaccination had passed off, prevents the "taking" of a vaccination when injected at the same time. This serum also possesses therapeutic power when injected later.

Anthrax.—This was among the first diseases to be experimented upon, and, as early as 1880, Toussaint published an article relating to the immunity from anthrax acquired as the result of protective inoculation. Toussaint's method consisted in inoculating sheep with defibrinated blood from an animal dead from anthrax, either filtering it through paper or heating it to 55° C.

Pasteur found that a single attack of anthrax protected the animal from subsequent attacks, and working along the line of protective inoculations he found that grown in a high temperature the anthrax bacillus did not form spores, and also lost its virulence. Cultures so attenuated he used experimentally on sheep, and succeeded in producing immunity. This was in 1891. Chaveau in 1892 found that blood of animals dead from anthrax, heated to 50° C. for fifteen minutes, could be used as safely and with as good results as Pasteur's vaccine, and had the advantage of being much more easily prepared and used. The tip of a vaccine-point being covered with the blood, several scratches with it sufficed to vaccinate the animal. Subsequently, he found that the preparation required more care than he had at first thought, so he returned to cultures, using bouillon-cultures attenuated by heat. The use of the vaccine was put to a practical test in certain districts where anthrax had been particularly prevalent, and the results were very gratifying, the death-rate being reduced from 7.03 to twenty-four hundredths per cent. Chamberland collected statistics of ten years of vaccination by Pasteur's methods, and found that where the mortality had been about ten per cent. in sheep and five per cent. in cattle, it had been lowered to ninety-four hundredths per cent. in sheep and to thirty-four hundredths per cent. in cattle.

The first experiments in the serum-therapy of anthrax were published by two Japanese bacteriologists, Ogata and Jasuhara. They made two important discoveries which subsequent experiments by other investigators have failed to substantiate. They claimed to have attenuated the anthrax-bacillus by growing it in the blood-serum of resistant animals, as the frog, rat, and dog, and that mice inoculated with frog- or dog-serum before infection recovered and were afterward immune. Sclavo of Rome, using the blood-serum of goats highly immunized against anthrax, succeeded in conferring partial immunity, and announced that after infection the serum prolonged the life of the animals—several days longer than the control-animals.

The latest report comes from Marchoux, working under the direction of Roux. He finds that the serum of sheep, highly immunized by attenuated cultures, and subsequently by large quantities of virulent cultures, produces immunity in eight hours, but that it wears off in three days. It is also curative, and as long as there is no

marked edema in the animals treated the results are good. From ten to twelve cubic centimeters are used. After the edema becomes marked the cases are not amenable to treatment. Marchoux believes that the serum causes an increased action on the part of the phagocytes.

Hydrophobia.—The exact cause of rabies is undetermined. Fae, Babe, and Gibier all thought that they had demonstrated an organism associated with the disease, but later investigations have not borne out their reports. The toxic substance, or virus, as it is generally called, is found in the brain, spinal cord, nerves, and saliva of infected animals, and the disease is transmitted from animal to animal by inoculations of these. Pasteur in 1885 found that by exposing infected cords to the air their virulence was gradually lost, and he conceived the idea of producing immunity and curing the disease in a manner similar to his anthrax method. A glycerin-emulsion of a cord that has remained for twelve days in a dry atmosphere is generally used to begin with, and stronger and stronger cords are then used, until the animal can take an emulsion of the cord of a rabbit that has just died from the disease. Out of nearly a thousand cases treated during a period of five years, only fifty-eight have died.

The Italian, Centanni, succeeded in producing immunity by subjecting the cords to the action of an artificial gastric juice. After from twelve to twenty hours' digestion, the virus no longer kills, but produces immunity. In connection with Tizzoni, he succeeded in producing a blood-serum of high immunizing power. The dry precipitate of this, mixed with water, and injected into animals, produces immunity, and also exerts a curative effect on animals that have been bitten by rabid dogs.

The authors, as quoted by Sternberg, believe that this antitoxin possesses the following advantages over Pasteur's method: Applicability at any time during the period of incubation up to the moment of the appearance of symptoms of rabies; absolute absence of virulence or of any injurious action; very rapid treatment by the injection of one or several small doses of material; complete solubility, and consequently prompt absorption of the material, and its easy preservation in the dry condition.

Antitoxin prepared in this way has not been used on man as yet, but theoretically it seems very much better than the method now in vogue.

Malignant Growths.—A great deal of attention has been paid of late to the treatment of malignant growths by means of antistreptococcic and other serums. There has been considerable adverse criticism from many good authorities, who decry the experiments as useless. Still, in view of the fact that we have no means of successfully combating cancers that are inoperable, the experiments certainly can do no harm, and may be productive of great good.

Among the earliest experiments are those of Richet and Hericourt, who have done so much original work in scientific medicine. They prepared antimalignant-growth serum by the following procedure: An osteosarcoma was taken and thoroughly rubbed up with water in a mortar, and then strained through a cloth. This was injected into dogs and a donkey, and after about ten days they were bled. The serum was obtained in the usual manner. In April, 1895, they reported the results of their labors to the French Academy of Sciences. They had used the serum on two cases successfully, one being a recurrent costal osteosarcoma about the size of an orange. After forty days of treatment with 3 c.c. of serum a day, the growth had been absorbed, as had almost all of the cicatricial tissue. The second case was one of a tumor of the stomach, about the same size, which also disappeared under treatment.

Subsequently, in October, 1895, the same authors reported the following results after having used their serum on a large number of cases:

There is a diminution of pain, the cancerous ulcers dry up, assume a healthy, granular appearance, and in some cases attempt to cicatrize. There is also a decrease in the size of the growth and of the enlarged lymphatic glands, and the evolution of the case seems to be delayed. So much for the good side of the subject. Unfortunately, after about two months of improvement, which takes place in four-fifths of the cases, the disease breaks out afresh; new foci form and death ensues.

A case which the writer treated by the antimalignant-growth serum, prepared after the manner given above, resulted as did the majority of the cases just cited.

Emmerich and Schall, at almost the same time that Richet and Hericourt made their announcement, came to the front with their new treatment of cancer, which consisted of injections of serum from sheep previously injected with virulent cultures of the *Streptococcus erysipelatus.* An injection of from one to twenty-five cubic centimeters of the serum, according to the size of the growth, was made directly into the neoplasm. They reported a diminution in symptoms and, in some cases, complete absorption of the growth.

A very bitter discussion has since followed in the German medical journals concerning the practicability of the cure. Angerer of Munich made an extensive report on all the cases he had seen it tried upon, and in every case recurrence eventually took place. Many other observers have reported recurrences and bad results, although occasional reports of improvement and cure continue to be made. In November last, in connection with Zimmerman, Emmerich modified his treatment by injecting with the serum pure cultures of the erysipelas-coccus thirty-six hours old. By this method he claims better results. The method of preparation of their serum is given in full in the *Deutsche medicinische Wochenschrift* for November 14, 1895.

Gibier deposited three years ago with the Academy of Medicine, New York, a sealed envelope containing the outlines of the application of serum-therapy to cancer and syphilis, and since then claims to have gotten good results in recent but as yet uncompleted experiments.

Glanders.—In addition to what has been said concerning the diseases in man, there remain a few notes on the researches on diseases of animals. Most important of these is glanders, as it occasionally occurs in man. Babes reports the cure of several cases by the use of mallein, but the remedy is not used to any extent in the treatment of this affection, as far as the writer is able to ascertain.

Mallein is a glycerin-extract, analogous to tuberculin, prepared from bouillon-cultures of the *Bacillus malleus* or, better, according to Koch, from the growth of potatoes. It is useful, too, in diagnosing incipient glanders in the horse, 1 c. c. injected subcutaneously causing a sharp rise of temperature to 40° C. within from fifteen to eighteen hours if the animal has the disease.

Pleuropneumonia in cattle is protected against by inoculation of serum from the lungs of an affected animal, or from the serum around such an inoculation. This is the outcome of a method used by the natives on the shores of the Zambese, which was reported by Willems as early as 1852. The natives caused immunity in animals by forcing healthy animals to swallow the liquid from the pleural cavity of an animal recently dead from the disease. In France Pasteur's name is intimately connected with the researches on immunity in pleuropneumonia. The government has taken up the matter, and the disease is also protected against extensively in Australia and Southern Africa.

Foot-and-mouth Disease.—In this infectious disease of cattle and swine protection and curative inoculations have availed nothing, although Behla claims to have produced immunity in young pigs and lambs by injecting filtered saliva from affected animals in two-per-cent. carbolic acid.

Chicken-cholera.—Chickens affected with this disease, which is too well known to need description here, due to the *Bacillus septicemia hemorrhagica* of Hueppe, can be rendered immune by vaccinating with attenuated cultures of the bacillus. The attenuation is produced by inoculating a rabbit, which will die from septicemia produced by the organism. The blood of the rabbit is then used to vaccinate the chickens. Kitt was able to produce immunity by injections of blood-serum from immune hens, also by inoculations with the albumin and yolk of their eggs.

Symptomatic Anthrax.—In this disease, caused by a spore-formation, vaccination has been done with great success, especially in Switzerland, where the disease is most prevalent. The method used is vaccination with powdered muscles of animals recently dead from the disease. This is attenuated by heat. The same result can be obtained by attenuated cultures.

Influenza, in the horse, a disease due to a small bacillus, described by Schütz, is treated by inoculations of the blood of horses recovering from the disease. Researches in this disease were carried on by the War Department of the German government.

Hog-cholera is a disease that, in connection with the swine-plague, has been the result of extended experiments by a number of investigators, among them Salander, Smith, and Metschnikoff. They succeeded in partially immunizing rabbits and guinea-pigs by using increasing doses of attenuated cultures of the organism, and also by using blood-serum from protected animals.

Hog-erysipelas.—The mortality of swine from hog-erysipelas has been greatly reduced in France during the past eight or nine years by using protective inoculations of attenuated cultures obtained by passing the organism through rabbits, which greatly reduces its virulence. This method is the result of the researches of Pasteur and his confrères of the Pasteur Institute.

Lorenz, working with the blood-serum of protected animals, succeeded in immunizing, for a short time, other animals. Unfortunately, a toxic substance was developed in the blood of protected animals, which killed the animals experimented upon.

Serpent-venom.—Another form of immunity is that to the venom of serpents. This has been the subject of successful investigation by Cal-

mette, of the Lille Pasteur Institute, and independently by Frazer, of Edinburgh. Calmette found that animals could be rendered immune in two ways; first by injection of small quantities of serpent-venom, or else by injection of venom modified by chlorid of gold or chlorid of lime. These animals can then take several times the quantity of the poison without its producing any marked effect. Their blood also exerts a marked antitoxic action, and blood-serum from them exerts a marked immunizing action. Calmette has on hand a quantity of this serum that he sends out to those desiring to test it. This is prepared from horses immunized against the venom of snakes. It keeps well in a cool, dark place. A small amount of camphor is added to aid in preserving it. His directions for the treatment of the tests are as follows: The limb above the bite should be tightly tied with a handkerchief. The wound should be washed with a 1–60 solution of hypochlorid of lime. The dose of the serum is then injected into the subcutaneous tissue of the belly. From 10 to 20 c. c. is a dose. In addition to this 8 to 10 c. c. of the hypochlorid solution is given hypodermatically about the wound. After this the tourniquet may be removed. Coffee should be given to the patient and friction practised. Ammonia and alcohol should be avoided, as they interfere with the action of the serum.

Frazer has also made extensive researches in this direction. His results are practically the same as those obtained by Calmette. One interesting thing he did was to immunize a pregnant cat. The kittens, to which she gave birth shortly afterward, were also immune.

Alcoholism.—Toulouse reported in March before the Biological Society of France his experiments in regard to the curative action of an anti-alcoholic serum. He gave two dogs 40 grams of alcohol for a week, and from them prepared a blood-serum. Of this he gave 24 c. c. to a patient suffering from acute delirium tremens. On the following day there was a fall in temperature, and the mind of the patient became clear. He is now attempting to discover whether this action of the serum was due to its being anti-alcoholic, or whether it is a quality inherent in all serums.

CLINICAL MEMORANDUM.

CASES OF HEMATURIA.

By FREDERICK W. ROBBINS, M.D.,
DETROIT, MICH.

Hematuria, although only a symptom, nevertheless holds such a prominent place in the mind of the general practitioner as to be regarded frequently as a disease *per se*.

It should be noticed whether the blood comes with the first portion or last portion of urine, or be evenly mixed with the entire quantity; whether the urine be brown, dark, or light red. If the latter, and the hemorrhage is slight, the trouble is located in the bladder, or in front of it; but if the former, one cannot be certain that the bleeding is from the kidneys. If, however, pus be present, the location need not, as a rule, be looked for beyond the bladder. It is important to observe whether exercise has any effect in producing or increasing the hemorrhage. Such would be the case were there a foreign body in the kidney, ureter, or bladder; also, probably, if a well-developed malignant growth were present; but not in a tubercular kidney or bladder. Observe also whether the urine is perfectly clear at one time, and bloody at another; if the blood be evenly diffused or present in the form of clots.

Pain may be severe, acute, from plugging of the ureter with a clot, or the pressure of a sharp, foreign body, or dull grinding, or simply a sensitiveness on deep pressure. The kidneys should be carefully palpated, which can usually be accomplished if the patient lie on his back with his thighs flexed, and take a long breath, one hand being pressed in the flank up under the rib, the other down through the abdominal wall.

The general health and history of the patient must not be lost sight of, nor must the examiner fail to look for albumin, tissue-structures, and casts, with the microscope.

With all these points, and others, which are not mentioned, in mind, a diagnosis can often be arrived at, but even now uncertainty may exist, and it will be found desirable to complete the examination with the cystoscope. The four cases reported illustrate four types of hemorrhagic trouble, and have been under my care during the last three months.

Case I.—Mrs. T., age twenty-three, seen through the kindness of Dr. Winter, her family physician. Father and mother in splendid health, and other family history good; personally, has been a robust girl, normal weight 120 pounds; was confined about a year previous to my seeing her; delivery normal; first noticed occasional hematuria and loss of strength the latter part of August; clots were passed, rather small and irregular in shape, and at times pure blood. The bleeding had become very free and almost continuous when I saw the patient February 5th; she was very anemic, and, although able to come to the office, quite weak, and she had lost twenty pounds of flesh; no cough nor symptom of general disease; could elicit no pain over the kidneys; passed water every few minutes, and the urine was mixed with pus and blood. These symptoms pointed to the bladder. Through the rectum I could feel nothing and resorted to the cystoscope for more light on this mysterious case, which I feared would prove tubercular.

I applied ten-per-cent. cocain-solution to the urethra, injected six ounces of water, after first washing out the bladder with a solution of boric acid, and a very clear picture presented itself. The summit of the bladder (mucous membrane) was red, and the capillary blood-vessels traversing the bladder, in various directions, were very beautiful. This condition is typical of a catarrhal cystitis. In

no other respect was the larger portion of the bladder at all normal, but when examining the trigonum there was plainly seen, near the opening of the left ureter, a spherical grayish mass, which, when the instrument was held quiet, gradually settled down, but when thrown into motion came into sight at the same spot as before as if held by a small pedicle. This was plainly seen at each of the sittings. The bleeding was in no way changed by examination, and a week later, after dilating the urethra, I introduced my index-finger and felt several soft papillomata, not, however, as large as I had expected from the cystoscopic picture. The summits of these growths were covered with a phosphatic deposit. After thoroughly curetting with a curette and my finger-nail, the pain and bleeding at once ceased. I have seen the patient a number of times since, and on May 26th she reported that there had been no pain nor hemorrhage since the operation; no loss of control of the urine; and, although she had had whooping-cough, she had gained sixteen and one-half pounds of flesh. There is still a slight amount of pus in the urine.

Case II.—Mrs. P., aged fifty-three. Family history good. Has always been strong physically, except for several years, has been subject to rheumatic pains and torpidity of liver. Saw her first February 4, 1896; stools clay-colored; conjunctivæ yellow; urine is slightly brown, and contains blood-cells. At times blood is abundant, at other times urine is perfectly clear. Patient has absolutely no pain, and only an occasional small blood-clot; no enlargement of kidney; very slight sensitiveness on deep pressure over right kidney. Exercise did not seem materially to affect the hemorrhage, as keeping her in bed for two weeks made little, if any, difference. Cystoscopic examination showed blood coming from the right ureter. First I gave ergot with no effect, then gallic acid with same result, and then I grasped the true condition and gave large doses of sweet oil and alkaline waters with the salicylates and colchicum, which resulted in a gradual return to health. March 24th, stools are normal in color, also the conjunctivæ. The urine is still bloody at intervals of several days. One passage may be clear, and suddenly, with no evident cause, the next bloody. No pain, appetite good, and weight normal, 140 pounds. April 6th, patient nearly well; is drinking large quantities of Geneva water.

May 25th, perfectly well; urine normal since last report; fingers and toes slightly swollen—gouty, I believe; rides her wheel as easily as ever. My diagnosis in this case was that in a gouty individual there was catarrhal occlusion of the bile-ducts and congestion of the liver and kidney, with rupture of the small vessels in the kidney.

Case III.—April, 1896. Mr. P., aged twenty-nine; carpenter; married eighteen months; father and mother healthy. Three years ago he had malarial fever, since which time he has passed urine frequently. He first noticed hemorrhage before marriage; no venereal history. At first bleeding was slight and lasted about a week. During warm weather he has comparatively little hemorrhage, but it is severe when he is chilled. He now urinates every two hours; no clots. Blood well mixed with urine, sometimes red, at others, brown; pain over both kidneys, although not of the same severity at all times. Pain and hemorrhage have been continuous for three weeks; pulse, 116; temperature, 98.6°; very thin, and has slight cough. Patient is extremely nervous, has twitching of the eyelids, and can sit still but a few minutes at a time. Cystoscopic examination, under influence of cocain, produced very little pain, and no bleeding followed, although the bladder was irritated with the back of the instrument. Examination negative. Dr. F. Maas had previously found tubercle-bacilli in the urine. Diagnosis, renal tuberculosis.

Case IV.—Mr. M., aged seventy-two. General insurance. April 10th. Three years ago I treated Mr. M. for a severe colic (renal). He recovered nicely, and one year ago had an attack of hematuria lasting for a few days only, and believed to be the result of acute renal congestion from a cold. A week ago he had what he thought was blood in the urine in the morning. In the afternoon he came to me and the urine was perfectly clear, with no albumin, casts, or cells present. Urine passed at office yesterday, six days later, was slightly cloudy, and this morning reddish-brown, with much albumin, blood, and tissue-cells present. Sound detected nothing in bladder, but right kidney is enlarged, reaching nearly to crest of ilium, hard, and nodulated, but freely movable. In general condition he is thin and very anemic. Has been growing weaker for several months, but has been attending to office duties.

Later in April Mr. M. had a severe attack of pain, during which the pulse went down below 50, and became very weak and irregular.

Diagnosis, carcinoma of kidney, but on account of his age and anemic condition an operation was not urged. Dr. McGraw of Detroit and Dr. Henrotin of Chicago concurred in the diagnosis and advice.

MEDICAL PROGRESS.

Operation for Luxation of the Peroneal Tendons.—Tendon-luxations are rare conditions, but when they do occur they are troublesome to treat. The peroneal tendons are most apt to be affected on account of their length and the angle at which they bend about the external malleolus, this being about 160°. If the groove in the bone is shallower than usual a predisposing cause exists which can be overcome only with difficulty. The tendons slip out under the influence of a sudden strain in the positions of abduction, pronation, and extension. There is a tearing sensation as the fibrous sheath gives way, and walking is possible, though painful. Rest and bandaging for five or six weeks may serve to reëstablish the tendons in position, but relapse is likely to occur. For habitual cases operation offers the only hope of cure. The tendons have been kept in place by an artificially stitched sheath, and in one instance the periosteal groove was divided and reflected, the groove chiseled deeper, and the periosteum replaced. But a much simpler and very ingenious operation has been devised by Kousmine of Kazan, and a case upon which it has successfully been employed is reported in the *Revue de Chirurgie* for September, 1896, by his assistant, Perimoff. The periosteum of the external malleolus

is first exposed and then a narrow trapezoid piece of periosteum and bone is elevated into a perpendicular position. The base of this flap is the posterior margin of the external surface of the external malleolus. The dressing of plaster of Paris was changed on the seventeenth day, the nails removed, and a new splint applied. The recovery was such that the patient, who had been prevented from walking by pain and lack of control over his foot, occasioned by the constant slipping of the tendons, was enabled to walk without discomfort and the tendons did not again slip out.

Operative Surgery in Phthisis.—In an article published in the *Mittheil. aus d. Grenzgebiet d. Med. u. Chir., Bd. I, Heft* 2, QUINCKE discusses the pros and cons of operations upon the tuberculous lung. The following procedures have been employed: (1) Aspiration of abscesses and injection of medicinal agents have been performed rarely and with doubtful results. (2) In ten cases an abscess-cavity has been opened and drained. In one case only was the operation carried out in two stages. In only three of these ten cases did the wound heal. In others a sinus persisted, or the patient died of extension of his disease, or was lost sight of. In several instances drainage was unsatisfactory on account of the situation of the fistula. (3) Excision of the affected portion of the lung has been performed by Lawson, Tuffien, Reclus, and Doyen. This is a dangerous operation, and even if successful the prospect for radical cure is remote. (4) In light of this experience the author recommends an operation intended to favor the spontaneous closure of an abscess-cavity. Such operative assistance has been rendered in two instances in which the surgeon has resected portions of the neighboring ribs without opening the cavity. The hope was that when the bony, resisting thorax-wall was removed from over the abscess, cicatricial contraction in the lung would be found. One of the patients operated upon was cured, and the other showed an improvement, but died ten months later during the administration of chloroform previous to the opening of a new-formed abscess. Quincke recommends this last form of operation.

THERAPEUTIC NOTES.

Croup and Diphtheria in Austria.—The Vienna correspondent of the *Münchener medicinische Wochenschrift*, June 30, 1896, p. 625, relates that during the month of February, 1896, 4424 cases of croup and diphtheria occurred throughout the whole of Austria, with 982 deaths—22.1 per cent., and 895 remaining under treatment. Among 1128 of this number treated with the antitoxic serum there were 149 deaths—13.2 per cent., while among 1849 treated otherwise there were 704 deaths —38.1 per cent.

The Treatment of Diphtheria With Antitoxin.—DUPUY, (*Progrès Medicale*, 1896, No. 27, p. 3) relates that from the year 1889 the mortality from diphtheria at Saint Denis gradually declined until 1893, when it commenced again to rise. During the first three quarters of the year 1895 there occurred only twenty-six cases, with three deaths. In June and September there were no cases at all. In October there were three, in November seven, and in December twenty-four. In January, 1896, there were sixteen. Of these last fifty cases diphtheria-bacilli were found in forty. These cases were isolated and treated with the antitoxin, with a mortality of fifteen per cent., as compared with previous records of sixty-six per cent. The six fatal cases were all of grave type, and would have elicited an unfavorable prognosis under any treatment.

Protogen is the name given by BLUM (*Berliner klinische Wochenschrift*, 1896, No. 27, p. 601) to a group of soluble, incoagulable albuminoid bodies, prepared synthetically by the action of formaldehyde upon serum-albumin and ovalbumin. A study of ovoprotogen shows that this substance is readily absorbed and well tolerated, and that it is capable of acting as a source of heat and of nitrogen for the body. It has the great advantage over ordinary albumin of being soluble in hot and cold water. Experiments upon dogs show further that by means of the subcutaneous use of protogen it is possible to maintain the bodily nutrition for at least a considerable time.

Incontinence of Urine and its Treatment by Suggestion. As the result of a clinical study CULLERRE (*Archives de Neurologie*, 1896, No. 7, p. 1) has reached the conclusion that essential incontinence of urine in children and adolescents is a neuropathic stigma, in general, benign but which may be at times the precursor of nervous disorders more or less grave, as neurasthenia, hysteria, hypochondriasis, mental obsession, with preoccupations, or fixed ideas, relative to the urinary function. The patients usually belong to families in which the neuropathic tendency appears in various forms, but not especially as mental alienation. They often display evidences of degeneration, physical and moral. Incontinence of urine is transmissible by heredity. Incontinence of urine is the result of a psychic disturbance similar to that observed in hysteria. The mechanism of the development of this morbid phenomenon appears to consist at the beginning in a sort of cerebral distraction. The center controlling the act of micturition fails in its function, or is uninfluenced by the medulla, or is, perhaps, inhibited by some peripheral excitation. This phenomenon, impressed upon the imagination of the subject, induces constant preoccupation which enters into the subconscious psychic sphere and provokes autosuggestions or impressions that aggravate the disorder and increase the frequency of its occurrence. Hypnotic suggestion is the most rational as well as the most efficacious mode of treatment, leading to recovery in seventy-five per cent. of cases. The degree of hypnosis is of little significance. A state of simple psychic passivity, with the eyes closed, may be sufficient. The treatment is efficacious at all ages, but the result appears to be the more certain the older the patient. Even in those not cured the influence of suggestion is evident, but it is neutralized by autosuggestions. In these patients the nervous disturbance is more profound, and hysterical stigmata are often present. Medicinal or surgical treatment when efficacious is so through indirect suggestion.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, NOVEMBER 21, 1896.

ROOSEVELT HOSPITAL AS A PRIVATE SANITARIUM.

"The Trustees of Roosevelt Hospital have completed and equipped a Private Patients' Pavilion for the treatment of surgical, gynecological, and medical cases under the most approved conditions. Care has been taken to furnish the rooms in such a manner as to render them cheerful, homelike, and attractive to those of the most cultivated tastes."

Such is the announcement which the trustees of this hospital have recently distributed generally to the medical profession and laity of New York. In accordance with the modern commercial custom of retail stores, and especially mammoth, omnivending caravansaries, an "opening day" is also announced, on which day "single rooms and rooms *en suite*" will be on exhibition. "You and your friends, ladies included, are cordially invited to visit and inspect."

In all candor and honesty of motive we humbly ask in the name of public charity what imperative exigency can induce the managers of a great public hospital, built and endowed with money consecrated to benevolence and charity, to use those funds to build and equip sumptuous accommodations for the wealthy classes, who alone can afford to occupy them? And with equal sincerity, in the name of the medical profession, we ask why such inducements should be held out to private patients to leave their usual medical adviser for the purpose of securing these luxurious accommodations?

THE DISSEMINATION OF SYPHILIS.

Bayet has been investigating the origin and spread of syphilis in Brussels and, at the last annual session of the Royal Society of Medical and Natural Sciences of that city, he reported his conclusions, which may well be called startling. In Copenhagen and Berlin, where exact statistics of the disease are kept, there are over four new cases annually to every one thousand of the population. And since most of these are about twenty years of age, they may be said to have an average of thirty years yet to live, which would place the figures for the total syphilitics of Berlin at any one time at 150,000, a tenth of the population. When one considers also that many cases are never treated, and that from one-fourth to one-fifth of cases of tertiary syphilis deny all acute symptoms, it is no wonder that Bayet concludes that syphilis holds the second place as a cause of sickness—surpassed only by tuberculosis.

In 114 instances of recent syphilis which came under his personal observation in Brussels, the history of contagion was obtained, and in only thirty per cent. was it found that the syphilis had been acquired from prostitutes, while in fifty per cent. it was obtained from waitresses in cafés, and women who were described as being "off color," *de mœurs légères*," though not subject to police inspection. In the remainder of the cases the infection was attributed to wives, mistresses, and others.

Bayet is of the opinion that if the class of women (waitresses, etc.), which stands on the border line of prostitution, and which was responsible for the infection in half of his cases, could be brought under governmental supervision, syphilis in Brussels would diminish. This does not seem so clear from his own figures, for the low percentage of cases derived from prostitutes seems

due not so much to their freedom from the disease, as to their small number, for, at the time of his investigation, there were only 200 in the whole city, while the number of women in his second group must have exceeded that figure many times.

FILTRATION AND THE LOUISVILLE WATER-SUPPLY.

Dr. W. D. White, Health Officer of Louisville, has published a small pamphlet—a reprint from the *American Practitioner and News*—in which he discusses the necessity of filtration in the treatment of water-supplies derived from the great rivers. He says of the supply of Louisville, taken from the Ohio River, that in its unpurified condition it cannot be classed among safe potable waters. Before it reaches Louisville, the Ohio River receives the sewage and surface-drainage from many cities and towns, aggregating a population of, probably, two millions of people. The result of this contamination is forcibly illustrated by the vital statistics compiled from official reports of health departments. Of the three principal cities taking their water-supply from the Ohio River or its tributaries, the death-rates from typhoid fever are reported to be, for the calendar year 1895, Pittsburg, 77 per 100,000 population; Cincinnati, 36 per 100,000 population; Louisville, 77 per 100,000 population.

On the other hand, in New York, Boston, and Brooklyn, which depend upon impounded water gathered in large reservoirs and carried in storage for many months, the typhoid-fever death-rates are by the last reports: New York, 17 per 100,000 population; Boston, 28 per 100,000; Brooklyn, 16 per 100,000 population. And in Vienna and Munich, where the water is obtained from springs in mountainous districts, the death-rate from typhoid is reduced to 7.0 and 7.1 respectively per 100,000 population.

Sedimentation and filtration may not furnish chemically and bacterially pure water, but, viewed from a practical standpoint, water thus treated will be so purified and disease-germs so much arrested that at present this method commends itself as the best means of purification. The introduction of filters at Hamburg is credited with reducing the death-rate in typhoid fever from 28 to 6 per 100,000 population. After the filters of the London waterworks were operated to meet the requirements of a bacteriological standard, the typhoid mortality was reduced from nearly 90 deaths per 100,000 of population for the decade 1860–70, to 24 for the decade 1870–80, to 19 for the decade 1880–90, and finally to 15 per 100,000 of the population for the period of 1890–94. In the recent discourse by Dr. Frankland before the Royal Institute of London, referring to the uniformly excellent filtration that had been reached in the water-supply of London since filtration was made compulsory in 1856, he said: "The effect of sand-filtration, as carried out by the London water companies, upon the living matter contained in raw water was simply astounding. A single drop of unfiltered Thames water sometimes contains nearly three thousand separate living organisms, but after filtration, only two or three can be found, and sometimes the filtered water is absolutely sterile." Mr. Hazen, late chemist of the Massachusetts State Board of Health, states: "In parts of Germany where the water is of exceptional purity and under governmental control, typhoid fever has nearly ceased to exist." The change of source from the two-mile to the four-mile intake-crib of the Chicago water-supply reduced the typhoid-fever death-rate from 104 in 1892 to 42 and 31 in 1893 and 1894 respectively, per 100,000 population.

The Louisville Water Company is at present making tests of the various systems of filtration, and is exhibiting a commendable desire, by persistent and intelligent investigations, to ascertain the best method of purification, with the purpose of constructing a filtration-plant that will supply a quality of water equal, as far as practicable, to that of any large city in the country. It is somewhat startling to know that Louisville still has such antiquated facilities as wells and pumps, of which there are 653. Their condemnation and destruction cannot come too quickly.

RECENT PROGRESS IN DERMATOLOGY.

ALOPECIA AREATA.

Is alopecia areata a nervous disease of the scalp, or is it due to a parasite? This question has been much discussed, and now Sabouraud, to

whom we owe so much for his investigations of ringworm, endeavors to answer it in a series of papers in the *Annales de Dermatologie et de Syphiligraphie*, 1896; vii, 253, et seq. He firmly believes that the disease is contagious, and that barbers' instruments are the most common carriers of the contagion; but as customers come and go from one barber to another, it is difficult to trace each case to its source. Starting with the theory of the microbic origin of the disease, Sabouraud has worked out a strong chain of evidence in its support.

He tells us that the typical hair of alopecia areata is found at the edge of an advancing patch, and is a stump of long hair that has remained in the scalp. It is club-shaped, or like an interrogation point. Its diameter becomes less as we go toward the root, and its color is lost. These hairs are always a sign of an advancing patch, and are not found in old patches. The medullary canal of these hairs is normal above, altered in the middle, and completely wanting at the root. The root is not bulbous and hollowed for the papilla, but in the form of a turnip. The fact that the hair changes from above downward, from a normal to a lanugo hair, is evidence that there is a progressive atrophic change in the papilla. Clubbed hairs are seen in other diseases of the scalp, but they are not friable like those of alopecia areata, in which the hairs split both transversely and vertically. In the frayed and broken hairs we often find the microbes commonly found in seborrhea. These are not the cause of the disease.

A study of the terminal period of the disease, when the hair tends to reform, shows that many hair-follicles have completely disappeared. Around the remaining ones the connective tissue is thickened, crowded, strewn with connective-tissue cells. At the base of the old follicle there are a great number of flattened, degenerated cells—*mastzellen*. Many of the hairs are in process of regeneration, and about them the sebaceous glands are large, sometimes enormous. The pigment-function of the skin remains suspended until complete recovery of the patch.

In the stage of complete absence of hair, a sheath of migratory cells encloses each hair-follicle, giving the appearance of a special folliculitis causing the disease. A hard and dense connective tissue about the follicles is a further sign of an inflammatory process. About one-third of the abnormal cells are *mastzellen*, which are found through the whole preparation always about the vessels, and specially about the hair-follicles and sweat-glands. These indicate a trouble with the nutrition, and that alopecia is not a disease of the hair, but of the skin of the hairy regions. Microbes are rarely found except when due to irritant treatment. It is probable that the interference with the hair-formation is due to a toxin developed from a microbe, which may be present at a distant part. In the upper one-third of the diseased follicles, between the junction of the sebaceous glands and the follicular orifice, there is a very equal ampullar dilatation about three-tenths of a mm. wide and one-half mm. high. The follicular orifice is of the usual size. Its upper end appears like a cupola, pierced by a round window. The sides are formed by the follicular walls, whose mucous layers are extremely flattened and atrophied. Its lower end is rounded, or slightly conical. Just below it the excretory duct of the sebaceous gland and the follicular canal merge together. This formation, Sabouraud names the *utricule peladique*. He regards it as characteristic of the disease, specially in its earlier stages, as when actual baldness sets in the shape of the utricule is already deformed. As we pass away from the bald area out into the surrounding skin, follicles in course of renovation become less numerous, and dead hair with full bulbs more abundant. Utricules that are full and closed are found among the sound hairs. They are filled with joined strata of epidermic cells, and contain in their centers, like a larva in a cocoon, compact clusters of microbes, a pure culture of the smallest bacillus known. It is constant in the utricule, and is named the microbacillus of the *utricule peladique*. It is almost punctiform in size. As it grows old it may be one-quarter mm. wide and one-half to one mm. long, and comma-shaped, or bent. The young bacilli are a little swollen in the center, and their ends are blunt. Usually they are neither agminated nor in chains. Each utricule contains millions of them. As long as the tops of the utricules re-

main uninjured the bacilli remain pure, otherwise there is a mixture of microörganisms. Exceptionally they are found in follicles that contain some remains of hair, but they rarely come into contact with the hair. This bacillus is regarded as the probable cause of the disease.

Sabouraud's theory is that the hair-follicles are invaded by this bacillus and the utricule formed. In a few days reaction about the utricule shows itself by the afflux of round mononuclear cells, which form irregular strata about the same. Then a mass of the same sort of cells collects about the vessels, from which they escape by diapedesis. Soon the follicles, both within and without the utricule, become surrounded by a thick mass of the same sort of cells, mixed with which are some *mastzellen*. Then progressive atrophy of the hair-follicles takes place, the papillæ die, and the hair is expelled. Now the utricule has lost its proper microbe, and becomes the habitat of various microbes. After a variable time the process ceases, and restitution may take place. This course of events shows the uselessness of local antiseptics in treatment, as when the bald patch is present there are no proper bacilli to act on. It indicates the usefulness of revulsives to hasten regeneration of the hair, and of epilation about the patch, and disinfection of the skin in the neighborhood of the patches.

It is not claimed by our author that this bacillus is proven to be *the* cause of the disease, but only that it is the *probable* cause. Certainly suggestive of the casual connection is the fact that it is abundantly present during the spread of the disease, and disappears when baldness is established. At present it cannot be distinguished from that of Unna and others, which is found in comedo, acne, and fatty forms of seborrhea.

This contribution of Sabouraud's is one of the most important of recent years. Of late the opinion has been gaining ground that in some cases alopecia areata is contagious, and probably parasitic. If his observations are found to be correct by the investigations of himself and others, we shall have another disease to add to our growing list of parasitic diseases, and a clearer idea of what we must accomplish therapeutically.

George Thomas Jackson, M.D.

ECHOES AND NEWS.

Starvation in London.—Seventy-one persons died of starvation in London, England, in 1895.

Long Island College Hospital.—The Chair of Medical Jurisprudence in this institution has been accepted by Judge Willard Bartlett, in the place of the late Judge Calvin E. Platt.

Newark's New Hospital.—The city hospital which Newark proposes to erect, at a cost of nearly $300,000, will be built very soon, as the contractors' estimates are now in the hands of the building committee.

Sir William MacCormac.—Sir William MacCormac, who has been ill with pneumonia, continues to have fever and suffers great prostration. His illness is a source of much anxiety to his many friends and admirers.

Cerebro-spinal Meningitis in Berlin.—For several years Berlin has enjoyed a respite from the ravages of meningitis, but during the last few months it has reappeared, and is attracting the studious attention of her physicians.

Colored Nurses.—The New Orleans University Medical School has in contemplation a plan for establishing a training-school for negroes. The suggestion has received cordial support, and there are good reasons for believing that the undertaking will succeed.

The Stille Medical Society.—The Stille Medical Society of the University of Pennsylvania has in press an elaborate history of its work for the last twenty-one years, and complete statistics of its members, among whom are some of the most prominent of Philadelphia physicians.

Another Object-lesson.—In Spain there exist no laws making vaccination against smallpox compulsory, and in consequence her capital is now sorely afflicted with this disease. The chief fatality occurs among young children, in the majority of whom vaccination has been wholly neglected.

Aldermen Blocking Sanitation.—The Brooklyn Board of Aldermen has refused to approve the bill of $7000 which Health Commissioner Emery contracted at the direction of Mayor Wurster during the warm weather, when he was obliged to employ experts to examine into the condition of the water.

The Mutter Lectureship.—The thirteenth course of the Mütter Lectureship, consisting of ten lectures on surgical pathology by Dr. Oscar H. Allis of Philadelphia, began in the hall of the Mütter Museum, Philadelphia, on November 18th, to continue till December 16th. The subject is "Dislocation of the Major Joints."

Rinderpest in South Africa.—The Governor of the Cape Colony has engaged Professor Koch, the bacteriologist, and Dr. Kohlstocher, the German medical adviser for East Africa and the tropical malaria regions, to go to South Africa to investigate the causes of the rinderpest, which has become wide-spread in South Africa.

A New Chemical Element.—M. Barrière believes that he has discovered a new chemical element in the course of his investigations in monazite-sand, and has named it lucium. It does not form insoluble salts when coming into contact with either sodium or potassium sulphate. Its spectrum resembles somewhat that of erbium.

A County Sued for an Error in Diagnosis.—Agents of the County Health Board decided that Charles Schulz of Union Hill, N. J., and his family had smallpox, and sent them to the hospital for contagious diseases at Snake Hill. The medical authorities at the hospital discovered no symptoms of the disease, and Schulz now sues for $7000 damages.

Jenner Centennial Celebration in Russia.—The coronation of the Czar so preoccupied the attention of the Russian people that it was decided to postpone from May to December the centennial ceremonies celebrating the discovery of vaccination. The 3d of next month, accordingly, has been selected, and it is hoped that the Czar will publicly participate in the rejoicing.

The X-ray Surpassed.—It is unofficially announced in Paris and Vienna that a ray with far greater penetrating power than that of Röntgen's has been discovered by Professor Donneun de Syke. Photographs are said to have been taken through a plate of iron eight inches in thickness, and many other substances that are opaque to the X-rays offer very slight obstruction to the passage of this new form of radiation.

A New Scottish Medical Journal.—The desire expressed by Scottish members of the medical profession for a fuller representation of Scottish work and teaching in all departments of medicine has culminated in the determination to launch the *Scottish Medical and Surgical Journal* in January, 1897. It will be issued monthly, and will be edited by Dr. William Russell, assistant physician to the Royal Infirmary, Edinburgh.

Our Profession Unappreciated.—Many physicians in Russia charge only 15 cents for a consultation and, although their number is small, suicides are frequent among them, the cause being inability to make a living. It is to be hoped that not the least of the benefits to grow out of the approaching meeting of the International Medical Congress, at Moscow, will be an elevation of the medical profession in the estimation of this nation.

Jefferson Medical College.—Mr. William Potter who has just been elected President of the Jefferson Medical College and Hospital, at Philadelphia, was United States Ambassador to Italy during a part of the Harrison administration. He was born in 1852, was educated at the University of Pennsylvania and abroad, and for the eighteen years before 1892 was his father's partner in a large manufacturing business in Philadelphia.

Medical Students and Temperance.—The British Medical Temperance Association recently gave a breakfast to the medical students, at which all the medical schools of London were represented. Sir B. W. Richardson, who presided at this function, stated that within the last five months eighty-eight medical students had been enrolled as associates, and that all were total abstainers. A prize of £5 is offered by the association for the best essay by a student upon "The Action of Alcohol on Digestion and Nutrition."

Unnecessary Extravagance.—The Health Board of Paterson, N. J., has received permission from the Public Library to destroy all books belonging to the latter that are found at any time in the hands of those suffering from infectious diseases. It has been conclusively demonstrated, as shown by an article in the MEDICAL NEWS, August 8, 1896, p. 152, that books may be easily, quickly, and thoroughly disinfected by formalin-vapor. It is no longer necessary, therefore, to destroy valuable books that have been exposed to infection.

Obituary.—Dr. Thomas H. Burchard died in New York November 14th. He was the son of the late Rev. Dr. Samuel D. Burchard, and was born in New York in 1850. Dr. Burchard was a graduate of Bellevue Hospital Medical College, was for a time house-surgeon at Bellevue, and was surgeon of the Twenty-second Regiment. He was made chairman of the Civil Service Commission at its first organization in the State of New York. At the time of his death he was lecturer on surgical emergencies at Bellevue, and attending surgeon at the City Hospital on Blackwell's Island. As early as 1873 he advised the removal of the vermiform appendix in acute perforative perityphlitis.

Cottages for the Insane.—The contract has been let for the erection of seven cottages at King's Park, L. I., for the reception of the insane patients who now overtax the capacity of the Long Island State Hospitals. The so-called cottages are to embody the most modern ideas in the facilities furnished for the care of mental patients, and their appointments will leave nothing to be desired from a scientific and sanitary standpoint. They will accommodate 864 inmates, and are to be completed in about eighteen months. According to the agreement made by the Commission in Lunacy, the Flatbush Asylum must be vacated in five years, which will probably lead to an extensive use of the cottage-system if the present experiment proves the promised success.

A Tribute to Vaccination.—Another proof of the value of vaccination comes from the Indian School at Carson, Nev. When the school reassembled in the fall of 1895, it was found that several pupils had, during vacation, been exposed to smallpox and had returned to school before it had developed. Every one in the school was immediately vaccinated, and the two pest-houses, hastily constructed, were soon filled with twenty-three patients. As many more with a mild form of the disease were cared for in the school-hospital. Many were quite sick, and yet not one case was fatal, and the school was continued throughout the year. Later came an epidemic of la grippe, which in six cases developed into consumption, of which four have died, and the other two can live but a short time.

The Estimate of Ginseng in Asia.—*The Lancet* is authority for the following statements concerning ginseng: It is regarded as the panacea throughout Eastern Asia, and is esteemed as a universal remedy, far above powdered tiger-teeth, the scrapings of young deer-horns, or even broth made from dog's flesh. Ten large and eight small sticks of ginseng, weighing collectively nine and one-fifth ounces, cost in the Chinese market nearly $1700. The wild plant is preferred, and is worth its weight in gold. Chinese farms devoted to its culture are most carefully supervised by watchmen employed night and day. A decoction is made from the root that is prescribed in all cases of debility, but it is chiefly prized for its aphrodisiac effect. A fortune awaits the enterprising American who will furnish the Chinese market from the abundant fields of our Southern States.

Unhealthy City Bake-shops.—The Bureau of Statistics of Labor of the State of New York has just issued its thirteenth annual report, which deals at more length with the bake-shops in New York City particularly than any other branch of industry. The report says that fevers, contagious and uncontagious, prevailed among many of the bakers who worked in basement- or cellar-bakeries; that most of the latter were unhealthy, and many of them very filthy. Since 1895 there has been legislation which tends to remedy some of the evils complained of. No new cellar-bakeries can be established, and there are laws regulating the sanitation, height of ceilings, hours of work, and other matters. The Board of Health of San Francisco is making vigorous efforts to remedy the same evil. It would seem that the dirty bakery, with its attendant evils, is the rule rather than the exception.

Bacteriology as a Regular Part of the Curriculum.—A very spicy bit of writing is the following, in the London *Lancet*, by a "General Practitioner"—not that he loves bacteriology more, but that he loves the medical politician less: "Bacteriology has been revolutionizing surgery and medicine for the last twenty-five years, but its study is not yet included in our curriculum, and the demand for its inclusion even now sounds rather like the voice of one crying in the wilderness. The threatened creation of a handful of opponents in the shape of registered midwives raises a prompt and spontaneous whirlwind of agitation. We are too commercial, and much too unscientific, or our souls would be stirred more over bacteriology and less over midwives. It is almost incredible that a subject of such vital importance should remain unrecognized so long. Will our grave and reverend seniors wake up of their own accord, or will they wait for the great British public to shake them?"

Street-cleaning and the Press.—Most men with a mission are misunderstood by the tradition-ridden public, and not infrequently are held to account for the deeds of fanatical followers, for which they are not directly responsible. In the criticism of Commissioner Waring given below, the New York *Press* would have been more in accord with reliable observation had it avoided the insinuation of incapacity on his part: "The Anti-Rubbish Association's work is possibly of sufficient aid to the Street-cleaning Department to warrant Colonel Waring's tribute of 'immense.' But is it desirable, even in aid of so worthy a cause, that little children should pick up the decayed vegetables and other dangerous objects with which his department is unable to deal?" Whatever varying opinions may be entertained as to methods, no champion of cleanliness, no advocate of sound sanitation, and certainly no observant physician, would withhold the just meed of praise from a department bravely battling in a cause that makes, more than all else, for our municipal purity, prosperity, and progress.

CORRESPONDENCE.

THE FRENCH SURGICAL CONGRESS.

PARIS, October 26, 1896.

Last week the French Surgical Society held its tenth annual session here and discussed some of the questions that are interesting French surgeons just now. One is, and yet is not, surprised to find that the general topics of discussion are about those that would come up under the same circumstances in the United States, though a patriotic American cannot help feeling that it is the more advanced phases of these same surgical questions that divide opinions with us.

The President's opening address was on asepsis, its methods and technique, and its results. He hailed with pleasure its gradual substitution for antisepsis in France. The second day was taken up with a discussion of the treatment of clubfoot. There were many arguments pro and con regarding the employment of Phelps' method and modifications of it. As in Europe generally, French orthopedists are divided rather sharply into two schools. The one holds, as Martin of Geneva put it at the Congress, "that operations are almost never necessary for patients under ten years of age, graduated manipulations, properly directed exercise, massage, and electricity, with carefully fitted apparatus, being all-sufficient," or, as Redard insisted, "that operations for clubfoot are very much abused, and that all that is needed at most is forcible correction under an anesthetic and then apparatus." The other school was well represented by Championnière, a surgeon rather than an orthopedist, who removes or sections everything that will prevent correction, begins passive movement as soon as the wound is healed, and never uses apparatus. Professor Péan was almost alone in the opinion that the proper course was the happy medium between these extremes—the judicious blending of operative and mechanical procedures that is almost the universal teaching of American orthopedic surgeons.

Dr. Chipault of Paris described his method of "apophyseal ligature" for the correction of spinal curvature, whether kyphotic or scoliotic. He fastens a wire suture to the vertebral apophysis, just above the deformity, and then passes it successively around each of the displaced apophyses while the spine is extended by two assistants, one holding the patient beneath the axillæ, the other by the feet. The vertebræ are thus wired into position and careful precautions taken to keep them there until the

tendency to deformity is overcome. The procedure has given excellent results in rachitic and scoliotic curvatures and in the first stages of Potts' disease.

Dr. Larger (of Maison Lafitte) presented two patients on whom a new method of cheiloplasty had been performed. In one, from whom one-third of the lower lip had been removed for epithelioma, the result was excellent, and the patient could even *whistle*. In the other, two-thirds of the lower lip had been removed, and the functional result was perfect; the deformity was only slightly noticeable. He takes a flap from the upper lip by an angular incision to and from the ala nasi, making a new angle to the mouth. The procedure has been done on both sides by Guinard, after complete removal of the lower lip, with very satisfactory cosmetic effect.

Dr. Schwartz of Paris reviewed the twenty-four cases of successful suture of large veins so far reported, and added a case of suture of the lateral sinus done during the course of a trephining operation, with no untoward symptoms afterward, and every reason to believe that the sinus had been left patulous.

Dr. Abadie of Paris called attention to the fact that in exophthalmic goitre the vaso-dilators seem to be disturbed only in the region supplied by the cervical sympathetic, notably in the thyroid itself and in the exophthalmos. He suggests that these disturbances, as well as the tachycardia, may be due to irritation of the cervical sympathetic.

Dr. Jonnesco of Bucharest reported two cases of removal of the cervical sympathetic from the superior to the inferior cervical ganglion, inclusive. In both cases there was immediate amelioration of all the symptoms, and so far there has been no relapse. In neither case have there been any physiological symptoms caused by the removal, no anomalous sweating nor flushing, and no vomiting.

Dr. Kocher of Berne, in the discussion of Jonnesco's report, said that he had had a number of excellent results from the removal of the thyroid in exophthalmic goitre. Where the prominence of the eyeballs leaves the cornea unprotected and liable to slough, some operation like this should be tried.

On Friday Dr. Kocher did a radical cure for hernia by his method before the members of the Congress, at the Necker hospital. It commends itself by its simplicity and, as Kocher has reported six hundred operations for radical cure, the last two hundred without a death, and as a relapse is a rare thing in his practice, it is very generally interesting. He frees the sac and brings it out through a new opening made in the line of the groin, a little above the internal ring, and sutures it there. He thus obliterates completely the peritoneal fossa that normally exists at the orifice of the internal ring, and stretches the peritoneum tightly over the orifice by traction on the sac. He then simply sutures the wound made to expose the sac. The operation takes but a few minutes.

After having used the Murphy button a good deal, most of the French surgeons are now using suture methods for intestinal anastomosis, and abandoning the button. This is especially true for gastro-intestinal anastomosis.

The last two days of the Congress were given up to the discussion of gynecology, and it seems to be as true in France as it is in America that

"Das Ewig-weibliche
Zieht uns hinan,"

for while many of the preceding sessions had been attended sparsely enough, the gynecological discussions were before a packed amphitheater.

The great question that divided opinions was, "Whether the vaginal or abdominal routes should be used in gynecological operations, especially as regards removal of the uterus." The greater safety of the vaginal operation makes it by far the most popular in France, and fibroid tumors that extend up to the umbilicus even are removed piecemeal through the vagina. It is not an esthetic operation to see; it is a bit of extremely hard manual labor to undertake in a warm operating-room; the general effect on vaginal tissues, as regards stretching and injury, must be worse than protracted, severe labor, but it gives excellent results, and is constantly growing in favor.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting October 19, 1896.

JOSEPH E. JANVRIN, M.D., President.

CHARLES H. CHETWOOD, M.D., read a paper on

THE TREATMENT OF FOLLICULAR ABSCESS OF THE FOSSA NAVICULARIS WITH ATTENDANT FISTULA.

This condition, he remarked, was not at all infrequent. It was generally obstinate to treatment, especially when the fistula was complete, that is, had both internal and external openings. Of late he had developed a mode of treatment which had given very satisfactory results.

There were three classes of abscess of the fossa navicularis, accompanied with fistula, met with in practice, *viz.:*

1. Follicular abscess with blind internal fistula.
2. Follicular abscess with blind external fistula.
3. Follicular abscess with complete fistula.

The etiology of these three varieties was the same—all resulting from urethral inflammation. The first class was the one most frequently met with, as it was the simplest to treat. The third class was often the result of an unwise incision of the urethral canal.

The symptoms of this condition were those resulting from a contracted meatus, induration at the fossa navicularis, and more or less profuse purulent discharge. The precise nature of the fistula present in any given case could be determined by injecting into the urethra a solution of hydrogen peroxid and the use of a wire speculum.

In speaking of the prognosis of abscess of the fossa navicularis, with attendant fistula, most authorities dwelt upon the obstinate character of the affection, and Dr. Chetwood quoted the words of Morson on genito-urinary diseases to this effect. Having referred to the operative procedures recommended in the books, he proceeded to describe his own method of treatment.

The patient was placed in a recumbent position in a

good light. Artificial light with reflectors might be employed, but ordinarily sunlight was all that was required for the purpose. At this first sitting it was usually best to secure complete anesthesia by means of cocain hydrochlorate. After this was done the wire speculum was introduced. An incision was then made internally over the site of the peri-urethral swelling, after which the urethra, as far as the end of the speculum, was packed with absorbent cotton. An ethereal twenty-five-per-cent. solution of hydrogen peroxid was then injected into the interior of the sac. Effervescence having freely taken place, the speculum was closed and withdrawn, dragging out the absorbed cotton in its grasp.

In the subsequent sittings the same procedure, with the exception of the incision, was repeated, and after the first one or two it was rarely necessary to use the cocain. Toward the end of the treatment the strength of the peroxid-of-hydrogen solution was reduced to five per cent., and as the fistula gradually healed the peroxid was applied by means of a pipette. The pipette he employed was made from an ordinary glass medicine dropper, which was brought to a proper shape by the blow-pipe.

The time required for the treatment in different cases varied from two to six or eight weeks.

The intervals between the successive treatments varied from two to four days. His experience with this method had led him to conclude that with proper care and attention all cases should result in a complete cure. In patients with a tubercular tendency the treatment was apt to be somewhat more tedious than in others.

The ethereal solution of peroxid of hydrogen which he employed was a proprietary preparation known as hydrozone. It was formerly known as ozonic ether.

Dr. Chetwood then proceeded to relate briefly the histories of three cases, which illustrated the three varieties of abscess with fistula which he had described, and in conclusion stated that the permanency of the cure by this method seemed to be established by the fact that he had had the opportunity of observing a considerable number of patients at intervals of from three months to one year after the cessation of treatment, and in not a single instance had there been any return of the trouble.

DR. HERMAN F. NORDEMANN said that the results described by Dr. Chetwood were certainly very gratifying, but at the same time he believed that equally good results could be obtained by means of a much simpler procedure than that treated of in the paper. In cases of this kind he thought that all we had to do was to scrap the hardened follicle out with a curette. It seemed to him that Dr. Chetwood's method was too complicated, and that unless the operator was a specialist he would hardly be able to carry out the required measures properly.

DR. CHETWOOD said in reply that he had no doubt that in acute cases of abscess with internal and external openings, a cure could be readily effected by means of incision or scraping; but such acute cases he would hardly regard as instances of fistula. It was in the chronic cases characterized by marked induration that we met with real fistula, and it was in these that the method which he had described was applicable. Many of the patients had suffered from this condition for years.

In regard to the hydrozone, he said that he disliked very much to make use of or recommend a proprietary article; but in looking up the literature of the subject he had found that this preparation had been discovered as long ago as 1868, by Dr. Richardson of London, while making some experiments with peroxid of hydrogen. After nearly thirty years a manufacturing chemist had taken it up and put it on the market as his own. There could be no doubt, he thought, that the ethereal solution was greatly superior to the watery solutions of the peroxids.

HENRY ILLOWAY, M.D., read a paper on

CARDIAC DISTURBANCES FROM GASTRIC IRRITATION.

It was an established fact, he said, that organic disease of the heart is apt to impair the functions of the stomach, as well as those of the liver, kidneys, and other organs. It was also well known that in advanced stages of organic cardiac diseases any undue distension of the stomach will immediately produce very serious disturbances. It was not so generally recognized, however, that gastric irritation is capable of producing, by reflex action, functional disturbances—sometimes of quite a severe type—of a perfectly sound heart.

Dr. Illoway then proceeded to narrate a number of cases illustrative of this point. The first was that of a married lady whom he found, when summoned to attend her, suffering from severe headache, nausea, and great weakness. The history showed that in returning from a funeral she had, with a party of friends, stopped at a wayside public house and partaken freely of ham sandwiches, cheese, and beer. He found that the temperature was slightly elevated and the pulse 75, and intermitting. A careful examination of the heart revealed nothing more than this intermission at irregular intervals. From his previous knowledge of the patient and the history given, he came to the conclusion that the stomach was the organ at fault, and that the cardiac irritation was produced reflexly by the gastric irritation. Under a carefully regulated diet, at first consisting only of milk and lime-water in small quantities, and the use of minute doses of tincture of nux vomica and Fowler's solution, she rapidly improved, and on the fifth day the stomach having in great measure regained its tone, and the cardiac irregularity having entirely disappeared, the patient was allowed to eat a little broiled steak. At the end of a week she was up and about, and taking her ordinary diet. For nearly six years afterward this lady was under his observation, being attended in several confinements, and he always found her heart in excellent condition.

The second case was that of a married lady of thirty, who had had three children. When called to see her he found her very despondent. She had been in poor health for some time, and the practitioner who had been attending her had told her that she had heart-disease, and cautioned her against going out, as she might at any moment fall dead. The patient was pregnant again, being about five months gone. She vomited after every meal and frequently in the intervals. After eating she had a sense of

oppression and suffered from an embarrassment of respiration, which was relieved after she vomited. Her bowels were inclined to be constipated, her tongue heavily coated, and her pulse regular, but rather feeble. In pregnancy he believed there were ordinarily present some dilatations and hypertrophy of the heart, and, taking her condition into consideration, he found the cardiac dimensions normal. At the apex, which was somewhat pushed up, there was at times heard with the first sound a slight whistling or blowing, which did not seem to him to have the characteristics of an organic mitral murmur. The heart's action was somewhat feeble, but the other sounds were entirely normal. From the general appearance of the patient and the result of his examination he concluded that the heart itself was in good condition, and that the symptoms from which the patient suffered were due in reality to the stomach, although she made no complaints of gastric disturbance, and stated that she was rather a moderate eater. In the hope of gaining more light upon the case, he observed her while she ate her dinner, and found that she took large quantities of greasy food, which she rapidly bolted. A quarter of an hour after the conclusion of the meal she began to vomit what she had eaten. In the vomit he noted large chunks of meat, which she had swallowed without mastication.

With this evidence at hand he had no hesitation in pronouncing the stomach at fault. He thereupon assured the patient that her heart was sound, and instructed her, instead of remaining in the house, as she had been advised, to go out and get plenty of fresh air and exercise. He also directed that but a small quantity of food —of proper character—should be taken at a time, and that the meals should be frequent. Medicinally he prescribed for her constipation, and to assist digestion and tone up her stomach ordered Dufresne's pancreatine with her meals, and small doses of nux vomica four times a day. Under this treatment she rapidly improved and soon recovered her cheerfulness. In four months' time she was delivered of twins, after a very easy labor, and made a quick recovery. Some time afterward he made an examination of her heart and found it perfectly normal, the whistling murmur having entirely disappeared. The patient was first seen in 1880, and she had remained in good health until the present day.

The third case was that of a general freight-agent, aged thirty-seven, who had married at twenty and now had his second wife. He was very corpulent. Ordinarily his weight was 206 pounds, but at the time he was first seen by Dr. Illoway, September, 1891, it was 186 pounds. His mother had been dyspeptic and somewhat rheumatic; his father healthy. He himself had never previously been sick, but was inclined to nervousness. During the past six months he had suffered from attacks in which a cold perspiration broke out on his forehead, his limbs became cold, and the circulation seemed to stop in his legs. The pulse was feeble, there was shortness of breath, and he had pain over the precardia. A sensation of fright and anxiety came over him and he felt as if his heart would stop and that he was going to die. These attacks, which occurred frequently, were generally promptly relieved by a drink of whisky, which he kept constantly about him. Several eminent practitioners had regarded these attacks as angina pectoris. One had prescribed nitroglycerin, another nitrate of amyl, and a third digitalis.

The patient presented a doughy appearance of countenance, with a pallid color, which had something of a cyanotic cast in it. He did not eat much during the day, but was fond of late suppers, consisting of such viands as gooseberries, deviled ham, lobster salad, smoked tongue, and pickles, together with considerable quantities of beer. His bowels were regular and his urine normal. He complained of pain over the hepatic region, and a gnawing sensation in the epigastrium. A careful examination of the thoracic organs revealed nothing abnormal.

A rigorous diet was prescribed, beer was prohibited, but he was allowed a glass or two per day of old Rhine wine and a small amount of whisky. At first the only drug ordered was sulphate of strychnia, but afterward he was given small doses of blue-mass, with rhubarb, and, on account of his nervous condition, asafetida to the extent of ten grains a day. Still later he took phosphate of soda and tincture of nux vomica. At times the patient was greatly relieved, and the attacks were much less frequent and severe. Occasionally, however, he would indulge freely in rich foods and beer, and always paid the penalty in a return of his trouble. After one of his attacks, in which he suffered very severely, he was given a prescription consisting of subnitrate of bismuth, bicarbonate of sodium, nitrate of strychnia, and caffein. For the paroxysm, instead of whisky, he was ordered to take lactopeptin and capsicum. The treatment finally resulted in his complete cure. The last time that Dr. Illoway saw the patient was in March, 1894, and he said that he had never had a return of his former trouble.

The inhibitory influence on the heart of the great vagus nerve, which also had a large distribution over the stomach, was described in all the text-books on physiology. It was not difficult to understand, therefore, that an irritation of the gastric filaments of the nerve, being reflected upward to the center, would be reflected back upon the heart and produce more or less arrest of action. This was clearly shown in the well-known laboratory-experiment of inhibiting cardiac action by striking with the handle of a scalpel the base of the intestines of a frog. In regard to case No. 2, the manner of the production of the disturbance was not as clear as in the other two narrated. That a valvular murmur may be produced by merely functional disturbance was now well established; but whether the disturbance in this instance was due mainly to nervous action or to the local pressure of a disturbed stomach, it was not easy to decide. That pressure, however, would play a prominent part in a case like this, when the patient was well advanced in pregnancy, could be readily understood. The stomach was undoubtedly in a state of atonicity, and would distend more markedly, even with the same amount of food, than an ordinary normal stomach, and in the case under consideration would have a greater morbid influence than under ordinary circumstances. While cardiac disturbance of an inhibitory character, due to gastric irritation, had not

as yet been reported, acceleration of the heart's action by reflex irritation from the intestinal tract had been noted, and this observation seemed to him to be of importance, as bearing upon prognosis, and also in relation to the matter of life-endurance.

DR. ROBERT NEWMAN said that the subject of the paper reminded him forcibly of some *post-mortem* examinations in which he had assisted as long ago as 1867. The autopsies were four in number. All were coroner's cases, and all were in large and corpulent men who had died suddenly. Two of them were very prominent citizens, whose death excited great surprise in the community. The observations of Dr. Illoway, he thought, offered a satisfactory explanation of these cases, which were otherwise difficult to understand. In none of these cases was there found any organic disease of the heart, but in all of them the stomach was distended with recent meals. In all of them also there was considerable adipose tissue pressing upon the heart and the stomach. It seemed to him now that if these patients, when the attack which proved fatal first came on, had been given an emetic, their lives might have been saved. If relief was not given in proper time such patients would die suddenly.

DR. WM. M. LESZYNSKY inquired of Dr. Newman if the kidneys had been found to be normal.

DR. NEWMAN replied that, as far as he could remember, the kidneys, as well as the heart, brain, and other organs, were entirely free from disease. As these were all coroner's cases, he believed that the *post-mortem* examinations had been pretty thorough.

DR. ILLOWAY, in concluding the discussion, said that the interesting cases referred to by Dr. Newman went to corroborate what he had said in regard to pressure playing an important part in cardiac disturbance. He had a number of other cases in his case-book bearing on this subject, which he would be glad to present to the Association at some future time, and in further elaboration of the matter he would take pleasure in incorporating in the paper a reference to Dr. Newman's cases.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

The Ninth Annual Meeting, held in Nashville, Tenn., November 10, 11, and 12, 1896.

FIRST DAY—MORNING SESSION.

THE Association met in the auditorium of the Nicholson House, and was called to order by the President, DR. E. S. LEWIS, of New Orleans, La. An address of welcome was delivered by the Hon. John Bell Keeble of Nashville, which was responded to by President Lewis. There were fifteen new members elected, after which the reading of papers began.

The first paper was read by W. D. HAGGARD, JR., M.D., of Nashville, Tenn., entitled:

VAGINAL VERSUS ABDOMINAL SECTION FOR PUS IN THE PELVIS.

He recounted the transitional periods in the treatment of pus in the pelvis: vaginal puncture, superseded by abdominal section, and removal of pyosalpinx; total uterine castration per vaginam by the French, and per abdominem by the American school. They have reluctantly given way to modern vaginal section, and evacuation and drainage of all pus-pockets. The abdominal route affords visual inspection of the field. The attack on morbid masses can be made with safety to visceral integrity. If pus-accumulations are multiple, rupture and peritoneal soilings are avoided, that is the supreme advantage of the vaginal route. He had often seen the pelvis deluged with pus with impunity. He had also seen patients die within twelve hours from fulminant sepsis, from peritoneal contamination. The cases perishing from sepsis on the third day are classical. There is no way of distinguishing these cases clinically. All should be regarded as virulent. The writer referred to a mortality of 18.5 per cent. in a series of collected cases of laparotomy for pus, done in five metropolitan hospitals in the last year, and asked what must it be in the "unheard-from precincts," and in the hands of the great unwashed? The abdominal method offers the best approach in tubercular inflammation of the ovaries and tubes, and in small unilateral pus-tubes.

The author referred to the advantages of exploring the pelvis for retro-uterine tumors, inflammatory, and adnexæ by vaginal section. The geography of pus in the pelvis in most cases makes vaginal incision extraperitoneal, a minor procedure giving major results, without shock, risk, or disturbance in convalescence. Patients will submit to it who will refuse more formidable procedures. We can change the methods, but we can't change the patient. In prolonged sepsis from huge abscesses, posterior section and drainage are a life-saving procedure. The special indications are in (1) early cases of acute suppurating salpingitis; (2) incipient post-puerperal peritonitis; (3) large pyosalpinx and true pelvic abscess. The first group includes early gonorrheal and abortional cases. The essayist had incised a tense tube and let out serous fluid and curetted a gonorrheal case of a month's standing with pain, temperature, and tenderness for three days. The opposite tube was normal. In a week that tube became similarly affected, and was similarly treated. He believed those serous effusions in the Fallopian tube were the preceding pathological condition to pyosalpinx. If this is true and it is the embryonal history of suppurating salpingitis in early gonorrheal and other inflammatory cases, the prophylactic value of vaginal section will be the greatest boon yet given to infected woman. In puerperal cases, incipient peritonitis, and puddles of pus in Douglas' space imperatively demand incision. Should simple pus-letting in any of these cases not effect a cure, subsequent operation for removal of the relics of previous ravages can be done without the dangers incurred in the presence of pus. The field of vaginal section is to prevent suppuration in early cases, to anticipate it in puerperal cases, and to save life in desperate cases. It is simple, surgical, and safe. Its application to the pelvic inflammatory processes and to pus in the pelvis is one of the greatest surgical triumphs of the age.

DR. JOSEPH TABER JOHNSON of Washington, D. C., said that while the vaginal method had a great many

points in its favor and was being resorted to more and more in cases of large pus-collections in the pelvis, yet those who had been familiar for a considerable time with the abdominal route, could operate more conveniently and dexterously by this method and with greater safety to the patient than by the vaginal method. He could not agree with the speaker that the vaginal operation may be done without any risk or damage to the patient. Sometimes in operating through the vagina for the purpose of removing the uterus and its adnexa, or for large pus-collections high up in the pelvis, where it is necessary to manipulate the parts a good deal, and to do a thorough enucleation, the surgeon was likely to tear the intestine, the bladder, the ureter, or rupture a large vessel which is out of sight. In such cases the abdominal is much safer than the vaginal route. However, the vaginal method has much to commend it in cases of pus-collections that are low down in the pelvis.

Dr. Charles P. Noble of Philadelphia believes we should practise a judicious eclecticism. He did not feel that either the abdominal or the vaginal method possessed all the advantages, but if restricted to one or the other he should choose the abdominal rather than the vaginal route. An objection formerly urged against the abdominal route was the large percentage of hernias which followed this method. Only a week since he had tabulated the operations he had done for four years, which amounted to 397 abdominal cases, in which he had used the buried suture in closing the abdominal wound. Of this number seven of the wounds suppurated, while 390 healed by primary union. Of the seven which suppurated, one had a hernia. Of the 390 cases, one had a large umbilical hernia. Aside from these two cases, he has not had any hernias in his operative work for the last four years, particularly where the buried suture was used. If the patient is in a condition to permit the surgeon to do ideal work, the question of hernia was such an insignificant one that it might be left out of consideration. The matter of hernia following abdominal operations was one of the stock arguments against the abdominal method. The next objection raised against the abdominal method was the great amount of shock as compared with the vaginal. His experience has been that unless the gynecologist operates on the desperately bad cases, shock played a small *rôle* in abdominal work. He had had more shock following vaginal than abdominal operations.

Dr. Howard A. Kelly of Baltimore, said that whenever possible, pus in the pelvis should be treated by vaginal puncture or section posterior to the cervix, without sacrificing any of the uterine appendages. A large percentage of the cases thus treated would have no future discomforts. Illustrative cases were cited. One of the principal arguments advanced by advocates of the vaginal route in removing the uterus, tubes, and ovaries, was the excellent drainage that could be secured by this method. In Dr. Kelly's opinion it is unnecessary to take out the uterus to get drainage. By making an incision posterior to the cervix and breaking up adhesions, free drainage could be established.

Dr. L. S. McMurtry of Louisville said a deep impression had been made upon the profession in the last few years by the vaginal method of operating for pus in the pelvis. The procedure, however, was by no means a new one. Battey, in his original operations upon the ovaries, attacked the pelvic organs through the vault of the vagina. The method of attacking accumulations of pus in the pelvis by vaginal puncture and drainage, practised by Kelly as far back as 1889, was the universal practice of abdominal surgeons for a long time. The sacrifice of the uterus in the majority of cases of suppurative pelvic inflammation was unnecessary. While there were undoubtedly puerperal cases with suppurative pelvic inflammation, where it was necessary to remove the uterus, it was not so to such an extent as to make it a rule that this organ should be taken out. Surgery should be confined within the limits of removing only such diseased tissue or organs as are necessary for a complete cure.

Dr. J. Wesley Bovee of Washington, D. C., objected to anterior colpotomy in dealing with pus-cases, unless the accumulation of pus was on top and in front of the bladder. He thought these cases could not be drained through the anterior vaginal route, and the pus could not be reached in many cases. He believes it is not necessary to remove the uterus at the same time pus-tubes are taken out. He had seen cases where there was an abscess of the ovary, an abscess of the Fallopian tube, and another alongside of each ovary, with three separate cavities on one side. By draining one, a large quantity of pus could be evacuated, and perhaps in some cases this would be all that was required. He did not want to be understood, however, as being opposed to the vaginal route in very urgent cases.

Dr. R. B. Maury of Memphis had during the last two years made it his duty to study thoroughly the subject of vaginal hysterectomy, as he had done quite a number of these operations without any mortality, without any accident, or unpleasant results. But he would not undertake to say that we ought to substitute it for laparotomy. Both abdominal and vaginal hysterectomy were operative measures that surgeons must avail themselves of according to the circumstances of the case. Dr. Maury then cited the histories of two cases that he had treated within the last thirty days, which illustrated the advantages of the two methods.

Dr. W. E. B. Davis of Birmingham, Ala., said the practice of incising pelvic abscesses was so old that it hardly required discussion, but the method of attacking pus-tubes by vaginal section was comparatively recent. Unquestionably, vaginal incision for pus confined to the tubes and ovaries would save these important organs in a good proportion of cases. In all cases of large pus-collections in the pelvis, the only thing that should be done was to incise the abscess and drain, and then later on the surgeon should be prepared to do an abdominal section, but he would rarely find occasion to do this. Total ablation of the uterus and its adnexa was unnecessary in many instances in which it was practised by some surgeons.

A. M. Cartledge, M.D., of Louisville read a paper on

CHOLELITHIASIS,

in which he reported several interesting cases. He

pointed out the diagnostic indications for cholecystostomy and cholecystenterostomy, and considered the former as the only operation applicable to the cases cited. In his opinion there were no cases that primarily demanded cholecystenterostomy. He was not prepared to say that this operation with the use of the Murphy button was good surgery, nor that the button was free from danger.

DR. JAMES MCFADDEN GASTON of Atlanta agreed with the essayist that in ordinary cases of gall-stones in the gall-bladder, with obstruction of the cystic duct, the simplest procedure was to lay open the abdominal wall, attach the gall-bladder to the incision, and remove the gall-stones. But in a large proportion of cases of complete obstruction he doubted whether there would be restoration of bile through the cystic duct into the gall-bladder. Relative to the comparative value of cholecystostomy and cholecystenterostomy, the two operations were applicable to entirely different conditions. No one would operate and expect benefit from a cholecystostomy, except to establish drainage for the bile in a case of permanent occlusion of the common duct, and this was the only condition in which the advocates of cholecystenterostomy had ever claimed anything for it.

DR. JOHN D. S. DAVIS of Birmingham emphasized the point that patients frequently have gall-stones without symptoms, more particularly jaundice. He does not believe that it is ever wise to resort to cholecystenterostomy as a primary procedure. The surgeon should first resort to drainage, and then if relaxation does not take place and the flow of bile is not effected, a cholecystenterostomy should be done.

DR. GEORGE BEN JOHNSTON of Richmond, Va., spoke of the diagnosis of gall-stones. He is convinced that if examinations of suspected cases of gall-stones were as careful and minute as they should be, surgeons would frequently find them. It has been his experience that enlargement of the gall-bladder does not always occur when a gall-stone exists, but that a condition which simulates enlargement of the gall-bladder frequently does exist, this condition being due to the presence of numerous dense adhesions found in the neighborhood of the gall-bladder, glueing it to every tissue with which it comes in contact. One thing which struck him as very singular in connection with the presence of gall-stones was, that the size of the stone or stones seems to make no difference in the production of symptoms. In regard to hemorrhage, it is generally admitted that cases in which cholemia is profound are the ones in which we are to expect hemorrhage, and by no known method can this hemorrhage be successfully controlled. He considers cholecystostomy a proper procedure in all cases, except in those where the obstruction is in the common duct and cannot be relieved.

DR. W. E. B. DAVIS of Birmingham said surgery of the gall-bladder for the removal of gall-stones had given brilliant results, but there were still questions in regard to operative procedures on the ducts that were not as yet definitely settled. He did not believe the essayist referred to cholecystostomy as being the choice of operation in a case where the obstruction of the duct could not be removed; that he must have had in mind the procedure advocated by Murphy of resorting to this operation in a case of stone in the gall-bladder where there was no obstruction in the duct. Murphy resorts to cholecystenterostomy instead of cholecystostomy, and he thought the essayist did not intend to convey the idea that he would not do a cholecystenterostomy where the obstruction in the duct could not be removed. Cholemic cases were bad to operate upon. Perhaps in not more than five or six per cent. of the cases is the obstruction found in the common duct. Some years ago the author made experiments which conclusively showed that the surgeon could incise the duct and drain with gauze without peritonitis following this procedure. A paper on this subject was read by him before the American Medical Association in 1892, since which time he had done further experimental operative work in which sutures were not used after the stone was removed from the duct, and while several of the cases were already very nearly dead from cholemia and eventually died, yet in the cases in which this method was resorted to, the abdominal cavity was walled off and peritonitis did not result.

DR. GEORGE A. BAXTER of Chattanooga directed attention to the frequency of gall-stones unattended with the ordinary symptoms of pain or colic, and cited an illustrative case in which there were found, *post mortem*, three large stones in the gall-bladder.

DR. F. W. MCRAE of Atlanta cited a case in which there were repeated attacks of colic with profound cholemia. An operation was undertaken with the idea that the obstruction was in the common duct, and that there were stones in the gall-bladder. On opening the abdomen in the presence of several physicians, he found the liver much enlarged and reaching almost to the umbilicus; but instead of finding the gall-bladder enlarged, he found a fibrous cord not larger than his index-finger. The common duct from disuse was reduced to a mere cord. A calculus was found in the hepatic duct, extending up into the transverse fissure of the liver. He did not know what to do for a case like this, and after consultation with his colleagues closed the abdomen. The patient died five days later from exhaustion. If anything could be done for such patients he would like to know it.

ORIGINAL ARTICLES.

SOME RECENT ADVANCES IN THE TREATMENT OF ATROPHIC RHINITIS.

BY RALPH W. SEISS, M.D.,
OF PHILADELPHIA;
PROFESSOR OF OTOLOGY IN THE PHILADELPHIA POLYCLINIC.

THE intranasal disease characterized by progressive interstitial destruction of tissue, by the formation of deep erosions, the loss of ciliated epithelium, and the many sequelæ of nasal sepsis, is still the opprobrium of the rhinologist. Recent changes in nasal therapeutics have however added greatly to our controlling power in this disease, and results can now be obtained, which, in the writer's experience, were quite impossible a few years past. In a paper published in the MEDICAL NEWS[1] more than nine years ago, the present writer discussed certain methods which were new, and which had yielded good results in his hands, but the prognosis given was "the best that can be done in advanced cases is to palliate or improve, and cleansing measures must be continued at intervals throughout the life of the individual to insure no active return of the disease." At the present time, although no means have been found of replacing lost turbinated tissue, much greater control can be gained over the cirrhotic process, and in early cases a large amount of permanent comfort for the patient can be secured. Perfect cleansing ranks first in importance in the treatment of atrophic catarrh, but it must be secured by methods which are not irritating in character. It should be remembered that atrophic rhinitis is characterized by migration of leucocytes, their organization into cicatricial tissue, and the subsequent contraction of the same; by the progressive conversion of ciliated epithelium into that of squamous type, and by the general loss of procreative cell-power.

Any form of cleansing or other treatment, therefore, which tends to produce any of the changes is the reverse of beneficial. The nasal douche as ordinarily used is nearly useless, and exceedingly apt to cause disease of the ears and accessary nasal sinuses, and the various forms of nasal syringe so frequently recommended nearly all cause much traumatism, except in highly trained and judicious hands. The best means at our disposal for clearing the nose of crusts is by the preliminary use of hydrogen peroxid. It is the habit of the writer to use about one dram of the three-per cent. solution in each nostril, employing a glass atomizer. The immediate effect is to fill the nasal cavity with a mass of bubbles, which cause the crusts to become so friable that their removal by atomization is an easy matter. A suitable instrument, throwing a coarse, abundant spray, and a pressure of from twenty to thirty pounds, is required for the cleansing process. The formula used is unimportant, so long as it be alkaline and antiseptic; the writer generally uses solutions of boric acid, sodium borate, and sodium chlorid. The spraying must be continued until every particle of exudate is removed, and the entire intranasal membrane is cleared, many minutes are frequently required to obtain this result, crust after crust being removed in turn by directing the nozzle of the atomizer against it. All rough measures, such as lifting off the dry crusts with forceps, or their forcible removal by the syringe, invariably leave extensive erosions, the tendency of which is greatly to increase the epithelial desquamation, with corresponding injury to the patient. Should the post-nasal space be so blocked by crusts that they cannot be removed by spraying through the anterior nares, the post-nasal syringe should be employed. The best instrument is a small Eustachian catheter mounted upon a syringe of about three drams capacity. This is gently introduced behind the palate, and the medicament injected vertically with some force.

After absolute cleansing has been secured, the most important measure at our command in the therapeutic management of atrophic rhinitis is the use of massage. Much absurd literature has been written about this procedure, several writers have given the number of strokes per minute, which, in their opinion, was absolutely necessary to secure a favorable result, and very elaborate directions have been given regarding the instrument used, etc. The principle, however, is simply one of mechanical vascular and cellular stimulation, which must never be carried to the point of causing inflammatory changes. Perhaps the best method is to wrap an aural cotton-carrier with a firm, fusiform tuft of cotton, about one

[1] MEDICAL NEWS, April 2, 1887.

inch in length, by one-sixteenth in diameter. This, having been well oiled, is introduced into the nasal chamber and brought in rather firm contact with the mucous membrane, the whole area is then rapidly and systematically rubbed, great care being taken not to bruise or hurt the parts in any way. Hemorrhage is always an unfortunate accident, as the resultant clot is difficult to remove, and invariably acts as an irritant. Massage may be continued for from three to six minutes, varying with the tolerance of the patient. Slight reaction usually occurs, the membrane becoming much redder. Medical stimulants in the form of ointments are conveniently used along with the massage, europhen in the form of a five- or ten-per-cent. ointment, cinnamon-oil from five to fifteen per cent. in albolene, and oil-solutions of thymol, are the formulæ giving most satisfaction. Any one of these may be used, the cotton masseur being dipped into the oil, which is thus applied with much thoroughness to the whole atrophic area.

Another very valuable method of stimulation is the use of the faradic current; this is best used by means of a long nasal electrode which can be carried back through the nose to the posterior pharyngeal wall; the positive pole should be used in the nasal cavity, the negative—a large sponge-rheophore—being held against the neck, or in the hand of the patient. The *séance* may occupy from five to ten minutes, real discomfort being always a signal for its discontinuance. I formerly used this method extensively, but now use nasal massage in preference to it, as the latter is a more manageable, less unpleasant, and more generally useful procedure.

Stimulation by means of cotton tents introduced into the nose and allowed to remain one or more days (Gottstein's method), has never given good results in the hands of the writer. They certainly seem to increase the amount of the epithelial desquamation, and unless applied with great care and frequently renewed, tend also to cause inflammatory changes and increased sepsis. As a rule, they are greatly disliked by patients, and have been abandoned in my practice. It may be stated that all persistent mechanical pressure within the nose tends to remove ciliated epithelium, and is consequently exceedingly prejudicial in atrophic rhinitis.

Among drugs which have given good results as stimulants in the treatment of this disease, thymol, in my opinion, still continues in the first rank; it may be used in watery solution with alcohol and glycerin, but is much better employed dissolved in one of the petroleum-oils, albolene, glymol, or benzoinol may be used, the thymol being in the proportion of from three to ten grains per ounce. The former strength can be borne by most patients, the latter only by a few in whom tolerance has been established by much previous treatment. Frontal headache, lachrymation, or a severe stinging sensation in the nose should always be regarded as indications for the use of a weaker solution. Numerous drugs may be usefully employed in combination with thymol, among them menthol, pine-needle-oil, and eucalyptus, in the strength of from one to three per cent. Sanguinaria and galanga were once much used as stimulants in this disease, but they are exceedingly apt to act as severe irritants, and owing to this and their unpleasant taste have been largely abandoned. Next to thymol, europhen has given the greatest satisfaction in the writer's hands; it may be used in the form of an ointment, as above suggested, or of a dusting-powder in combination with stearate of zinc; or in advanced cases, where marked stimulation is required, the pure, powdered europhen may be used. Although slightly less efficient than thymol in the average case, it suits some cases better, is always less painful, and its use may be regarded as one of the distinct advances in nasal therapeutics. Aristol, iodoform, and allied compounds are also a benefit, but have more disadvantages than the one first named. Cinnamon-oil has been shown to be the most decidedly antiseptic of the volatile oils, and is particularly valuable in conditions of nasal and pharyngeal sepsis; it may be used in the form of a spray, from three to ten per cent. being added to the ounce of albolene. It appears to be entirely unirritating, produces a grateful feeling in the nose, and its odor is pleasant and not persistent. Whichever oil-spray be employed, it is essential that it be thoroughly applied to a perfectly clean mucous membrane, a suitable apparatus, and a pressure of at least twenty-five pounds per inch are essential.

Stimulation may be easily overdone in cirrhotic catarrh by drugs as by mechanical means. MacDonald observes that "it is somewhat doubtful whether we are any more justified in stimulating the nasal mucous membrane in atrophic rhinitis than a cirrhotic liver"—the warning and the pathological suggestion contained in this sentence are both exceedingly valuable. It cannot too often be reiterated that all violent measures in this disease defeat themselves, by causing the very pathological processes which they are intended to cure. Purely surgical measures have but a limited value in cirrhotic catarrh; dead bone must be carefully removed, the minimum of

disturbance of surrounding tissues being carefully observed. Nasal spurs, or similar obstructions, should not be operated upon, and turbinated tissue should not be removed, except under cases of absolute necessity, the constant tendency to cicatrization and contraction in this disease never being lost sight of. I have seen several cases in which extensive intranasal operations had appeared to light up the atrophic process, and all operations on the turbinated tissues are to be regarded as at least unfortunate necessities. Jonathan Wright[1] has had a similar experience, and forcibly points out how in vascular engorgement cauterization or other intranasal operation does not restore the efficiency of the damaged muscular apparatus, but by the formation of a scar favors the tendency to fibrosis. The use of skin-grafts as suggested by Laborderie, at first sight, appears to be one of the most valuable surgical measures that have been brought forward in atrophic rhinitis, the very essential of the disease being the permanent loss of epithelium. Unfortunately, the only available grafts which have been suggested are those which are covered by squamous epithelium, such as the intradigital membrane of the frog, whereas what is wanted is a membrane covered with columnar ciliated epithelium. The writer's efforts to graft such a membrane have all been total failures, and it is doubtful whether it is possible to obtain this very desirable result. Laborderie claims that nearly half the number of grafts made from the skin of the frog take effect, and advises the use of from ten to twenty grafts in all advanced ulcerative cases. Even if this admirable result could be obtained by the average operator, a surface covered with pavement-cells, and incapable of ridding itself of adherent mucus, would be the effect, and the patient would be no better off than before.

The internal treatment of cirrhotic catarrh is not satisfactory; the only drug which can be considered to have the slightest specific effect is iodin. This may be given in the form of iron iodid or of potassium iodid, and certainly, in some cases, appears to lessen the tendency to inspiration and to exert a beneficial influence on the course of the disease. Tonics are, of course, needed in many cases, and hygienic measures are naturally of the first importance. Climatic change appears to arrest the disease in a certain proportion of cases, and, when possible, should be tried, especially after local treatment appears no longer beneficial.

Perhaps the most serious danger of advanced cases of nasal atrophy and suppuration is aural complications. A large proportion of cases have recurrent attacks of acute Eustachian salpingitis, a certain proportion of these going on to suppurative disease of the middle ear and perforation of the membrana tympani. Especially is this the case where the nasal douche, snuffing fluid from the hand, or similar measures in which hydrostatic pressure is brought to bear, have been employed. Colonies of streptococci are thus easily forced into the Eustachian tubes, with the result of setting up suppurative conditions extremely prejudicial to the welfare of the patient. With a view to the prevention of these complications, cleansing measures should always be by some such method as has been advised. Patients should also be carefully warned to avoid forcibly blowing the nose, as in this way the Eustachian tubes are also frequently infected. The use of Politzer's inflation is even more dangerous, and should never be employed in cases of cirrhotic catarrh until absolute cleansing and antisepsis of the nasal cavities have been carried out. If suppurative salpingitis is already established, the most satisfactory mode of treatment is by means of the Eustachian syringe-catheter. This should be introduced through the nose, and the folds of the tube carefully washed out with a warm, mild, antiseptic formula, boric acid and salt being commonly used by the writer. Treatment should be continued daily for some time, the tympanum being meanwhile *carefully let alone*, unless already actually diseased. If the middle ear be already involved, antiseptic irrigation and, if necessary, an early paracentesis should be performed. Recurrent acute attacks of suppuration almost certainly result, sooner or later, in thickening of the drum and ankylosis of the ossicles in all neglected cases, and deafness and tinnitus aurium are almost the rule in such. It is believed that by the faithful use of some of the newer methods of treatment which have been above suggested, better results can now be obtained in cirrhotic rhinitis than could be secured by any of the older forms. The prognosis of this dread disease is still, however, a very gloomy one, moderate improvement being all that can be hoped for in any advanced case; but great comfort, freedom from odor, arrest of the disease, and avoidance of complications can all be secured by patient treatment extending over not a few weeks, but many months. What, above all else, the rhinologist needs is some method of controlling fibrosis—the fibroblastic process. The nearer we come to securing this, the more will our chronic cases improve.

EXOPHTHALMIC GOITER TREATED BY GALVANISM, WITH REPORT OF CASES.

BY RALPH R. SPENCER, M.D.,
OF GRAND RAPIDS, MICH.

DURING the past five years I have had my attention particularly called to the study of that obscure and little-understood disease, exophthalmic goiter. From the frequency with which I have met the disease, I am led to think that it is commoner than formerly, and consequently should receive our attention. Writers on the subject since have only confirmed the original observations made by Dr. Robert J. Graves, *viz.*, that the rapid pulse, exophthalmos, and nervous symptoms often precede the development of goiter.

Though there are certain districts where goiter is endemic, I am not aware that the disease now under consideration is prevalent there; it more often appears in places where true goiter is comparatively rare. It is more common between the ages of twenty and thirty, though occasionally seen in those younger or older. Judging from the observations of many writers, it would seem to attack eighty per cent. more females than males. In eighteen years' practice I have seen but one case in the male. It has been the opinion of observers that the disease is more dangerous and rapidly fatal in men than in women. It has been my observation that the disease develops rapidly; that there is generally a history of some preceding cause of debility, as continued hemorrhage and diarrhea, excessive fatigue from overwork, mental or physical. There are many cases on record which have developed suddenly after extreme mental excitement, exertion, or shock.

In my practice I have had but one death from Graves' disease, and was unable to get consent of relatives to an autopsy. Increased vascularity, slight hemorrhages, and abscesses have been reported; it has also been shown that division of the restiform body gives rise to symptoms closely resembling those of exophthalmic goiter. The most plausible theory, and that accepted by a majority of the recent writers, is the one which attributes the disease to a primary lesion of the thyroid gland. The symptoms of thyroidism bear a very close resemblance to those of exophthalmic goiter, as emaciation, sweating, rapid pulse, tremors, and exophthalmos have all been observed. The prominence of the eyes, I believe, is due to a dilated condition of the blood-vessels; there is no marked deposit of intra-orbital fat; in fact, emaciation and anemia of the orbital region is the condition found.

Prognosis should be very guarded in well-marked cases. Little improvement has followed any treatment; while in mild cases some are restored to perfect health, others live for years, but are never strong, and are subject to frequent relapses. It has been my experience that the heart-tonics, such as digitalis, strophanthus, etc., do harm. During the past three years desiccated thyroids have been largely prescribed for the relief of all forms of goiter. I have prescribed them in four cases, with no other result than poisoning my patients, causing headaches and dizziness.

Thyroidectomy does not grow in favor with those who have resorted to the operation, and should be resorted to only in extreme cases.

Like many others, having had indifferent results from therapeutical agents used in this disease, I have of late given up dependence upon them, and resorted to electrotherapeutic treatment. For fifteen or twenty years past the treatment of exophthalmic goiter by the galvanic current has been generally growing in favor. I have found that the rules laid down by Cardew[1] for the administration of electricity produce satisfactory results, hence I have adhered to them, with some trifling changes: (1) Galvanism is superior to faradism; (2) weak currents are sufficient, two or three milliampères (I give more—ten or twenty); (3) each application should last six minutes; applications should be made two or three times a day. The anode should be placed on the back of the neck, over the seventh cervical vertebra; the cathode should be moved up and down the side of the neck, from the mastoid process along the course of the great nerves. I have also used it with the two poles pressed to either side of the goiter; also with the positive pole over the goiter, and the negative over the solar plexus, continuing the current about five or six minutes in each place. A nurse, or any competent person, with training, can administer the treatment, the doctor seeing the patient frequently. One's first experience is apt to be discouraging, as frequent relapses, from various causes, are sure to interrupt the recovery or improvement of the patient. The patients are neurotic, and susceptible to trifling impressions; these are cases where patience and perseverance, both on the part of the physician and patient, are usually rewarded by marked improvement in nearly all cases, the symptoms gradually disappearing. Cardew states, and I am willing to bear him out, "that we have in electricity an agent powerful for good in the great majority of cases of Graves' disease."

[1] London *Lancet*, July 4, 1892.

Such cases as fail to be benefited by it are, unfortunately, extremely unlikely to derive much benefit from any other therapeutical agent. It is cheaper than drugs, it can be left in the hands of the patient more safely than continued doses of digitalis and belladonna, and it can be continued a long time without doing harm, should it fail in doing good.

The following is a report of my cases:

CASE I.—February 3, 1893, girl, aged sixteen, student, had been ill two or three days with what her family thought to be la grippe. Just before my call her symptoms became alarming. I found a pale, slender girl, with large goiter and eyes that protruded nearly from their sockets; heart beating so tumultuously that the motion imparted to the chest-wall could be seen from across the room, and its sounds heard at some distance from the patient. The pulse was 160 and the temperature 106°; respirations, panting and rapid. Sedatives, belladonna, and cannabis indica were given, and cool sponge-bathing ordered; patient made no improvement, but, on the contrary, grew worse; temperature increased to 108°; she became delirious, and before midnight died from exhaustion induced by hyperpyrexia.

I was unable to get a good history of this case, as she had not been regularly under the care of any physician. She had suffered from nervous symptoms, goiter, and protruding eyes for two years before her death.

I was also unable to obtain consent of friends to an autopsy. This being the only fatal case I have seen, I report it to show what the symptoms are at the end of such a case.

CASE II.—August, 1893, Mary L., aged thirty unmarried, seamstress, was anemic and of slender build; parents living and healthy. Symptoms, goiter quite noticeable, heart rapid, but exophthalmos was not marked. Prescribed iron and manganese pills and began treating the patient at once with galvanic current, treating her for twenty minutes every second day. This patient made rapid improvement, and in two months was so well that she discontinued treatment. I have seen her once during the past year, when she informed me that her trouble never returned. Her health has been good since taking the treatment mentioned. This case I did not consider a serious one, and the patient was treated early, also taking a much-needed rest, which, no doubt, contributed largely to her prompt recovery. As she improved, menstruation, which had been absent for six months, returned.

CASE III.—Treated during the summer of 1894, Holland girl, aged eighteen, occupation a domestic. This patient, contrary to the usual rule, was not anemic, but had a good color and full habit; family history good.

The symptom which caused her to consult a physician was excessive sweating; her occupation exposed her to the heat of the kitchen, and her clothing was saturated all the time with perspiration, which emitted a sour and offensive odor. Other symptoms observed on examination were goiter and rapid pulse, most of the time as high as 120; menstruation scanty and irregular. Patient was treated by galvanism. Medicines given were potassium permanganate and belladonna; treatment continued for four months; goiter disappeared and heart-action reduced to 90; profuse sweating stopped and menstruation restored.

CASE IV.—January, 1896, boy ten years old, parents healthy, had suffered from a severe and protracted attack of rheumatism two years previously, which had left him with valvular affection of the heart. This was aggravated by a second attack, and within two weeks a goiter and exophthalmos became quite noticeable. The patient, being confined to the bed, received no electrical current, the treatment being directed wholly to relieving the rheumatism, which was accomplished in about four weeks. The boy still has a valvular murmur and goiter.

CASE V.—Miss L., aged twenty-five; occupation, public singer and instructor in music; family history good; became my patient during the summer of 1894. She gave the following history: During the preceding year, while a pupil in the Boston Conservatory of Music, she found she was suffering from bleeding piles, from which, at times, the hemorrhage was profuse; this having gone on for several months, she consulted Dr. H. O. Marcy of Boston, who took her into his private hospital and operated upon her successfully for their removal.

While in the hospital she began to develop exophthalmos, and within two months this symptom had changed her appearance so much that on her return to Michigan her friends sometimes failed to recognize her on the street.

I saw her soon after, and discovered that she also had goiter, a fact which had hitherto escaped her notice. Her condition gradually grew worse, rapid pulse, irregular menstruation, profuse sweating, and chronic diarrhea being her symptoms. In November she had become too weak to continue her singing and teaching, and by my advice tried complete rest in bed for several weeks, when, seeing no improvement, she was sent to a hospital, where she could have daily electrical treatment and massage. Improvement was rapid, and in about two months patient went home and treatment was discontinued until January of this year, when, finding her strength failing rapidly, she again came back for treatment. Galvanism and massage were used, and again marked improvement was noticed. Patient was treated once or twice a day for two months, and has gone home much improved. She has a twelve-cell battery, and will continue to apply galvanism as long as there is improvement.

During the last interval of treatment accurate measurements were taken, and the neck decreased in size one and one-half inches and the pulse from 140 to 90 and 100. Patient increased in strength, and, though not cured, was greatly improved.

In reporting the above cases I have not thought best to mention all the remedies that were tried and discarded, and have only mentioned those which were of apparent benefit, *viz.*, galvanism and massage. Three of the cases took desiccated thyroids faithfully, but in each of these the remedy did no good, but made the patient worse.

CASE VI.—September, 1895, Miss Z. R., aged eighteen, student; family history good. Physical signs were goiter and exophthalmos; on physical examination, the pulse was found to be small, 100 beats per minute, and greatly accelerated by the slightest exertion. Any considerable effort, as the climbing of one flight of stairs, would cause dyspnea and general distress; the sounds of the heart were not altered, except in the duration and force of the first sound. There was an absence of physical signs to prove the existence of any ordinary form of heart-disease; it was the ideal condition met with sometimes as a result of overwork producing cardiac exhaustion.

The symptoms described all developed within three weeks, and are of interest, because I believe the contributory cause was the abuse of the bicycle. The patient belongs to a family of bicyclers, her father being a dealer in that vehicle. It had been her custom to take many long and tiresome runs to adjoining towns, also to climb steep hills without dismounting, and she had repeatedly tired herself in this manner till forced to desist by the development of the symptoms described. In this patient the goiter, exophthalmos, and cardiac symptoms developed simultaneously. Rest in bed for several weeks, nutritious diet, and tonics improved the patient rapidly. She did not continue the treatment as long as she should have done, and at this time, though enjoying a fair degree of health, still has goiter and the eyes are not natural. She has not resumed the use of the wheel.

AN ADDRESS.

THE EVOLUTION OF THE SURGERY OF THE TWENTIETH CENTURY.[1]

BY GEORGE R. FOWLER, M.D.,
OF BROOKLYN, N. Y.;
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC,
SURGEON TO THE ST. MARY'S AND SENEY
HOSPITALS, BROOKLYN.

"The law is continuity, the watchword progress, the worker evolution."—PROFESSOR JOHN CHIENE, M.D.

IN availing myself of the privilege of appearing before you this evening, I desire to express my acknowledgments to the President for his invitation to deliver the anniversary address on behalf of the time-honored body of which I am proud to be an humble member, and to promise you, in return for the assurance which I see in your faces that you will listen with patience to what must be an old story to most of you, and, perhaps, will prove to be a prolix one to the remainder, that I shall endeavor so to clothe my subject as to make it appear more than a mere recital of facts, a catalog of events, a list of names, or a stilted declamation of so-called brilliant surgical exploits.

It is my purpose to consider particularly those events which stand out prominently before all others in their relation to the advances made in the science and art of surgery during the present century.

Material progress, however valuable, is but a symptom of mental development. This is just as true of medical science as of science in general, of which latter, in truth, we only just realize that we are but a part. We are but one of the spokes in the wheel of progress, and the conditions of development within our own workshop do not differ materially from those which obtain in the world of work at large. Little things, or what appear to be but insignificant events, gradually assume great importance, and that in direct proportion as they are of a character to enlarge our ideas and broaden our views; take, for example, the incident of the apple falling from the tree at the feet of Newton. The little ripple of thought thus set in motion in the pool of the philosopher's mind evolved into a wave, which gathered force as it rolled on until no man may say where its influence shall end. From this trifling incident arose a train of philosophic thought whose far-reaching effects have extended into the celestial spaces by establishing a physical law, to which the entire planetary system is as subject as the most insignificant object upon the earth's surface.

Looking back over the cultivated fields of the century, where the toilers of the soil of science have labored, how rich the harvest seems! And yet not all has even blossomed, much less come to fruition. The seed of original thought is being plenteously sown, and the graft of improvement implanted upon older stock. Here and there one discerns a constantly broadening area of exceptionally rich intellectual development, whose thought-nucleus glistens and sparkles like a jewel of great worth, as, indeed, it is. In the field of the healing art animal-experimentation, anesthesia, antisepsis and asepsis, and the discovery of the Röntgen rays, are to surgery what Newton's discovery of the law of the attraction of gravitation was to astronomy, Priestley and Scheele's discovery of oxygen to chemistry, and Darwin's discovery of the law of selection to evolution. From each of these, as a central idea, have grown out constantly widening furrow-lines of both intellectual evolution and physical development.

EXPERIMENTATION UPON LOWER ANIMALS.

The emblem "Truth" has ever been written upon the banner of the soldier of science. In the words of our lamented Loomis: "The scientific experimenter alone adds to our store of knowledge and power for good. He seeks for truth, and truth alone. However isolated

[1] Anniversary address delivered before the New York Academy of Medicine, November 19, 1896.

or unrelated his results may seem, he sees in each a potential value. The most insignificant discovery thus not only has its peculiar merit, but points the way to other hidden truths, although it may often be difficult to connect the several links in the long chain of progressive knowledge."[1] This sounds the key-note of all the important advances made in surgical science during the century. The spirit of original research is one of the most precious heritages of the healing art. But it is particularly during the past century that the results obtained from experimentation have been of the greatest value to surgery, although the intellectual evolution which led up to these results has been going on for centuries.

The fear of a fatal result from hemorrhage exercised a deterrent effect upon the operative efforts of the earlier surgeons, and at the present day this fear has a most healthful influence in preventing pretenders from performing surgical operations. Like a soldier under the enemy's fire, the surgeon, by his behavior in the presence of a severe hemorrhage, soon announces what qualities he possesses to entitle him to respect. As Senn has truly said: "Skilful treatment of hemorrhage is an infallible criterion of good surgery."[2] Loss of blood is the regular accompaniment of all major operations, and may complicate what at the outset was the most trivial procedure. It is no wonder, therefore, that the earliest practitioners of our art should have turned their attention to this most important subject; the evolution of the aseptic animal ligature is an outcome of this early demand for protection against the dangers of surgical hemorrhage.

The first application of the ligature for the prevention of hemorrhage was the result of an instinct rather than of reasoning. Naturally enough this instinct found its first expression in the arrest of the bleeding resulting from severing the umbilical cord in the new-born. The first account of such application dates back to 1500 B.C., although it is more than probable that this was the very first bit of technic that was developed in what was afterward to become the science and art of surgery, although writers in general allude to Hippocrates as the discoverer of the ligature. Through the centuries that have elapsed since the human maternal instinct first impelled the encircling of the navel-string by perhaps a twisted bit of bark or flax, or a lock of hair plucked from the mother's head, the history of the ligature has been the history of surgery.

It would be impossible to overestimate the force of the moral obligation which impels the surgeon to make sure, in every step of his work, that his actions bear upon their face the deep and lasting impress of honest effort. This obligation demands of him that all attainable knowledge bearing upon his work shall be at his command. Much of this knowledge must be obtained by experimentation, and every instinct of humanity demands that the subjects of this experimentation shall not be his fellow man, but rather those lower in the scale of animal life than himself. It was this moral obligation that impelled Hunter, near the close of the last century, to experiment upon dogs with the view of discovering the reasons for the frequency of secondary hemorrhage following the application of the ligature for the cure of aneurism, and it was this experimentation which developed the fact that injuries to arteries underwent ready repair when the vessels were healthy, and that it was only when diseased conditions were present, or arose, that ulceration and secondary hemorrhage took place. Hunter's enthusiasm was unbounded, and his love of truth so great that his death was directly due to a burst of righteous, yet passionate, indignation, when his word was doubted. He recognized that great benefits were to be derived from experimentation upon the lower animals. Not only were vast results obtained by his indefatigable labors; he furnished the stimulus for those who were to follow, and awakened a generous rivalry in other workers by his example. These followed up his work by confirming the results of his experiments, as well as instituting new ones.

At the beginning of the present century, much yet remained to be learned of the behavior of the blood-vessels under the application of the ligature. An alarming mortality from secondary hemorrhage confronted the surgeon. Preëxisting disease of the vessels could not account for this in all cases. In 1802 there appeared a most important publication by J. F. D. Jones, an English surgeon. Jones followed up the spirit of Hunter's inquiry by means of experiments upon animals, and made a most important addition to our knowledge of the processes employed by nature in suppressing hemorrhage from divided and punctured arteries. He showed that the effusion of lymph from the wound inflicted upon the artery by the ligature was sufficient, even if the ligature were removed at once, to obstruct the vessel; that the formation of a thrombus was not necessary to a complete obliteration of the latter; and, what is of great importance in the light of subsequent developments, he first directed attention to the deleterious effects of suppuration upon the processes of cicatrization in the blood-vessels.

Jones' momentary application of the ligature, however, proved to be unsafe, although its occasional success showed his experiments to be of the utmost importance. At this point the work was taken up by Travers (1813), who, still by means of experiments upon animals, made another stride in the march of progress. The same processes of intellectual evolution were still at work, and new light came from a repetition and extension of Jones' experiments. Travers substituted the temporary for the momentary ligature, and showed that the fears of the older surgeons concerning the dangers of too tightly constricting the artery, which led them to include bits of cork, or a roll of lint in the ligature, in order to prevent erosion of the vessel, were groundless. The great difficulty of determining the earliest possible moment when the ligature could be safely removed proved to be a complex problem, with all the unknown quantities concerned in the processes of healing entering into the consideration. To remove it too early meant disaster from hemorrhage, and to leave it on too long was but to invite suppuration, and possible ulceration of the vessel-wall. Moreover, the

[1] Presidential address of A. L. Loomis, M.D., LL.D., third meeting of the Congress of American Physicians.
[2] "Experimental Surgery."

manipulation necessary for the removal of the ligature seriously interfered with the prompt healing of the wound. In the following year (1814), Lawrence advocated cutting off the ends of the silk ligature, which theretofore had been left long and hanging in the wound to facilitate removal, and burying in the depths of the wound the loop of thread encircling the artery. The credit for this, however, has been claimed for Haire of Essex (1786). Following this came the use of animal ligatures—chamois-skin by Physick, catgut by Cooper, tendons by Paul Eve, human hair by Porta, and the successful use of metallic ligatures of various kinds by Levert. These latter were always cut short and allowed to remain permanently in the wound.

Slowly, but surely, the goal was being reached; but progress came exclusively along the line of accurate observation, and almost entirely upon the basis of experimentation upon animals. Finally the dark clouds of uncertainty cleared away and the clear, bright sunshine of established truth burst forth. The aseptic animal ligature was evolved as a part of Lister's wonderful achievement. The object of the search of the best minds in surgery for centuries was at last found. A ligature had developed which will fulfil all the purposes of hemostasis with certainty and safety, inflict the minimum amount of traumatism, produce the least amount of irritation—serving its purpose pending the completion of the healing process, yet finally disappearing by absorption and substitution when its office has ceased.

Another striking instance of the value to surgery of definite results, derived from experimentation upon animals, is shown in the advances made in our knowledge of processes of repair in osseous structures. The developments in this field alone have been of incalculable benefit to mankind. Duhamel's theory that the growth of bones takes place by an extension of their parts was far from satisfactory to Hunter. He therefore (1772) carried out his classical experiments upon the growth of bone by feeding pigs upon *Rubia tinctorum*, or madder, which has the property of coloring that portion of the bone which develops during the time the animal is fed upon the plant. By means of these and the additional experiments of embedding foreign bodies (shot) in the long bones of animals, at fixed distances from each other, he proved that Duhamel was in error, and that the growth of bones was accomplished by the addition of nutritious material and the simultaneous removal of old bone, the osseous structure in this way maintaining its form and the proper relation of its parts. Howship (1817) followed up this work, and by a series of experiments upon rabbits, made a most valuable contribution to the then existing knowledge of the processes of repair in fractures. He observed the effusion of blood in the neighborhood of the injury, the changes which this undergoes, the fact that it is the medium in which the ossific reparative processes are carried on, the imperative necessity for firm fixation in order that these be not interfered with, and the circumstances governing the quantity and seat of the ossific deposit. In 1836 the work was taken up by Syme, and in 1837 by Heine; in 1844 by Flourens, and later (1858–1863) by Ollier's classical observations and contributions to the physiology and surgery of the osseous system, particularly the osteogenetic properties of the periosteum.

In fact, commencing with Hunter's classical experiments in 1772, almost the entire knowledge of bone surgery at our disposal to-day has been worked out upon the lines first laid down by that great surgeon and those who came after them, including Hofmokl's studies upon the histology of bone during fetal life, and the observation that during the development of bone cartilage-cells are transformed into bone-cells (1874); Kassowitz's observations upon the deposit of early matter in the fibrillary reticulum (1879); Regal and Vignal's experimental researches, which showed that irritation of the periosteum resulted in the production of new bone from the medullary tissue beneath, without passing through the stage of cartilage, and the additional fact, that if the periosteum is destroyed its place is supplied by a connective-tissue cicatrix which resembles the periosteum and supplies its place in case fracture, is subsequently produced at the site of the former periosteal defect (1883); Kosmowski's observations upon the methods of repair in fractures of the skull, in which it is shown that to the osteogenetic properties of the medullary tissue are due the reparative processes in general, and the union of loose splinters of bone in particular; and P. Bruns' experiments upon autotransplantation of marrow which showed that formation of bone takes place from preëxisting osteoblasts in the marrow, a result which constitutes, according to Senn, a potent argument in favor of renewed efforts to obtain bony union in intracapsular fractures of the neck of the femur. Time will not permit me even to mention the names, much less dwell upon the labors of all those who have materially contributed to our store of information, by experiments upon animals in this most important branch of surgical science and art.

Nor will time permit more than a passing reference to these researches commencing with Galen's experiments upon the alimentary canal, and continuing through the intervening centuries until their fullest fructification was reached by the labors of that grand exponent of surgical truth, Nicholas Senn. Who does not know of the wonderful achievements of this man in intestinal surgery alone? Achievements that were made possible by that same development of moral and intellectual force which circles around and has evolved from that which has existed since the very beginning of man's need of aid from man. This precept has possessed the same cogency through all time and remains the golden rule of to-day! Nor can I more than allude to those truths that have been snatched from depths which have been deemed as unfathomable as the mystery of life itself, and that bid fair to rob tetanus of its terrors, hydrophobia of its horrors, and septicemia, in its various forms, of its thousands of victims yearly. Even that God-given boon, anesthesia, as I shall show further on, was evolved, in its final and consummate triumph, upon the basis of animal experimentation. With truth and love of fellow man as the aim and object, the imponderable forces of moral and intellectual development the motive power, and animal experimentation the means, the march of

progress has gone steadily on, and will go on in spite of those who would block the wheels of science by prohibitory laws, the result of a mistaken philanthropy and a misguided enthusiasm.

ANESTHESIA.

The thought-nucleus of anesthesia is found in the gradual evolution of the nervous system of man to its present high development. Around this cluster efforts at self-preservation and the instinct of protection against, and relief from, pain. Through countless ages the struggle went on, and with increased sensitiveness to external impressions came increased demand for means to assuage the pangs of injuries inflicted during combats with those natural foes encountered in the struggle for existence. With the evolution of powers of reasoning this instinct became fully developed, and it is possible for us to believe that methods of accomplishing the relief of pain, more or less completely, were known to the wandering tribes centuries before Abraham came down into Egypt, and are now among the lost arts.

* * * * * *

In Morton's discovery of anesthesia can be discerned the effects of that intellectual evolution which made possible the development of this aid to the surgeon's art. In the world of science there had already dawned a realization of the importance of untrammeled inquiry and the necessity for sound methods of investigation by experimentation, which should admit of verification at every stage of the process.

Of secondary interest is the story of the discovery of the anesthetic properties of chloroform. Flourens, the French physiologist, in 1847 related before the Academy of Sciences, how, after employing hydrochloric ether for purposes of anesthesia, he was led to experiment with chloroform, a substance closely allied to chloric ether. He was completely successful in anesthetizing animals during the otherwise most painful physiological experiments. About this time a student of Dr. John Bell, Furnell by name, who, subsequent to the announcement of the anesthetic effects of this agent, had been in the habit of inhaling ether, and from whom Bell, for fear that the young man would do himself some harm, had hidden the ether bottle, suggested to Mr. Holmes Coote the use of chloroform, a bottle of which he had found and experimented with upon himself while searching his master's medicine-chest for the missing ether-bottle. Dr. Bell seems to have learned of this accidental discovery of the properties of chloroform by his student, and to have imparted the knowledge to Waldie, the Liverpool druggist. It was upon a suggestion from the latter that Simpson made trial of this agent and soon satisfied himself of its valuable properties.

ANTISEPSIS AND ASEPSIS.

The discovery of anesthesia, marking, as it does, one era of the century now drawing rapidly to a close, stood out like a beacon-light and shone alone, albeit with a glorious effulgence, for a score of years, until the modest Scotch surgeon, Lister, wrenched another great secret from the rock of hiding of great truths, which awaited but the rod of such a Moses to bring it forth. The little spark first kindled in the wards of the Royal Infirmary at Glasgow, although at first almost quenched in the pitiless rainfall of ridicule, has survived and furnished the stimulus for other workers, and now stands glowing forth, casting its brightness upon a heretofore dark and unexplored ocean's waste, and lighting the way for other explorers.[1] Doubted and otherwise contemptuously treated by his own countrymen at first, with the exception of Jenner, no discoverer of modern times has had more to contend with in the attempt to place truth upon a certain foundation than Lister. The struggle, however, was a short one. Ere long the processes of evolution of the human mind, which had been at work slowly, but surely, since the days of such giant minds as Galileo and Newton, came to his aid. Without regard to the special details of Lister's method, the underlying principle was soon recognized with that unerring instinct which places first in importance any suggestion which broadens our thought as to the possibilities, however remote, of a new grasp upon the processes of Nature, and the application of knowledge thus gained to the needs of the human race.

Without detracting in the slightest from the glory of Lister's achievement, it is but fair to say that his was but the application of a principle, that of germ-growth, which was then in the process of development, to the solution of a problem that was uppermost in the minds of other workers. The peculiar conditions under which microorganisms proliferate being known, it was but a step further to the suggestion that these possessed irritating properties when brought in contact with tissues whose vital resistance had been lowered by the infliction of an injury. That the relation of germ-infection to wound-diseases did not first occur to Pasteur, is only to be explained upon the assumption that the evolutionary changes in the mind of the latter stopped short at the stage of the application of the germ-theory of disease to locally favorable conditions in the human body. His mental vision had grasped in succession the catalysis of Berzelius, the relation of fermentative processes to the growth of mold-fungi, the dependence of certain epidemic diseases in lower animals upon microörganisms of similar origin, and the possibilities of the laws of susceptibility and immunity. Here, however, his work, so far as it relates to surgical diseases, ceases, and at this point it is taken up by Lister. It is but the repetition of "the spectacle so often witnessed in the history of science of a brilliant discoverer traveling in triumph along some new path, but stopping just short of the goal which subsequent exploration has revealed. A great fact stands looming up before his face, but, through the excess of light which he has already taken in, he is blind to its presence. The intellectual effort already put forth has left no surplus for a more extensive sweep of comprehension, and further progress requires a new start and forces generated from a fresher

[1] "On a New Method of Treating Compound Fracture, Abscess, Etc., with Observations on the Conditions of Suppuration," by Joseph Lister, Esq., F.R.S., Professor of Surgery in the University of Glasgow, *The Lancet*, March 16, 23, and 30, 1867, pp. 326, 357, 387.

mind."[1] With faculties unjaded and unwarped, Lister appeared upon the scene. The long lines of thought devoted to studies of the growth and life-history of microscopically minute vegetable organisms led up logically to the inception of his task and its final consummation.

As a further stage of the evolution of moral forces based upon the element of safety, came an inquiry as to the effects of the antiseptic agents themselves upon the individual, and the behavior of the tissues, when contact with possible sources of infection were eliminated. Two facts were thus developed: (1) It was ascertained that the use of germicidal agents was a not unmixed good; (2) that the prevalence of pathogenic bacteria was not nearly as great as had been formerly supposed; and (3) that the tissues themselves, when uninjured, possessed a certain amount of resistance to the invasion and effects of these latter, the lessening of this resistance being in direct proportion to the extent of the injury inflicted upon the parts by the operation itself, or by whatever was brought into contact with them. With the study of the natural processes of repair, of tissue-resistance, and evolvement of the *locus minoris resistentiæ*, came the demand for the protection of living cells, and the evolution of asepsis. Slowly, but surely, this portion of the chain was forged and fashioned, until it stands as the connecting-link between the pound of cure of the past and the ounce of prevention of the future.

The last link of this chain to be worked out was the evolution of the aseptic conscience. The entire circle of protection thrown about the operating-field could be broken and every precaution set at naught by a lapse of watchfulness, or want of care on the part of any one of the participants in the operation. It was early recognized that constant vigilance was the price of safety, and hence arose the necessity of inculcation in the assistants by the operating surgeon of precept upon precept and line upon line. The knowledge derived from Cheyne's labors, that even the air of hospital-wards was comparatively free from noxious germ-life, led to the inquiry as to the sources of the infecting agents; and when it was realized that these were to be found in the skin of the patient, his clothing and hair, the hands, and particularly the finger-nails of the operator, the persons of nurses, and, in fact, everything with which the patient might come in contact, which had not been previously disinfected, the necessity for the most rigorously protective environment was declared and emphasized, and the responsibility of the operator increased. This extreme degree of surveillance was soon followed by a highly developed mental sensitiveness in those engaged in the work, which rendered them susceptible to and conscious of the slightest act calculated to impair the purity of the aseptic technic, either on their own part or that of others.

THE RÖNTGEN RAYS IN SURGERY.

Sound knowledge of pathology and correct diagnosis must always remain the groundwork for successful treatment, and no surgeon, however skilful as an operator, can hope to attain the acme of usefulness in his work without these. The substitution of accuracy for guesswork, of certainty for uncertainty, of positive knowledge for abstract theorizing, must ever be attractive to the scientific mind. The discovery of Professor Röntgen of Würzburg, within the past year, of the peculiar power of certain rays to pass through substances that are opaque to what we know as light, bids fair to be to surgical diagnosis what animal experimentation, anesthesia, and asepsis are to operative surgery.

The story of the discovery of the Röntgen rays reads almost like a chapter from one of Bulwer's tales. One night, while working in his laboratory with a Crookes' tube trying to fathom the mystery of the cathode rays, his attention was attracted by a piece of paper lying upon the work-table, upon which appeared a luminous, sparkling spot, as if a single ray of bright sunshine, coming through an opening in a dark shutter, had fallen upon it. This explanation of the phenomenon was manifestly impossible, since it was night. The reflection was too bright to proceed from his induction machine. Upon examining the piece of paper closely, he found that the reflected light had been given off from a portion of the sheet where some idle student in the laboratory had carelessly traced the letter "A" with a platinum-cyanid solution. He at once came to the conclusion that the illumination of the paper must have been caused by the rays from the cathode of the Crookes' tube, although these were invisible to the eye. The mind of the practical surgeon grasps at once the possibilities of not only detecting the presence of foreign bodies, but the relative positions of the fragments in fractures, and of articular surfaces in dislocations. Both the methods of immediate inspection by means of the fluoroscopic tube and screen, as well as permanent record through the medium of the skiagraphic plate, are already in use, and yet not a twelvemonth has elapsed since Professor Röntgen announced his discovery. One year ago to-night the possibilities of the application of this one of the results that have been evolved from the labors of Faraday, Maxwell, Hertz, Lenard, and Röntgen were scarcely dreamed of; and yet such has been the contention for the privileges of priority that practical methods have been rapidly brought forward, through the labors of Edison, Pupin, and others, for the utilization of this vast work for the purposes of practical surgery.

When we pause and gaze upon the magnificent structure that has risen during the present century, every stone of which represents the strength of a patient, earnest, and conscientious worker, cemented together only too often by the life-blood of the martyr, it is scarcely possible for the human mind to realize that so much could be accomplished in so short a time, much less grasp the possibilities of the future.

The lessons of the past gather about us like the falling leaves of a summer's departing glory, but they are not lost nor wasted. Properly interpreted, they serve to emphasize man's opportunity in the present and his hope for the future. Not the least among these lessons is that which teaches us that the unfolding of Nature's secrets is but a part of the plan of the creation; that irresistible

[1] Professor Fisk, "A Century's Progress in Science," *The Atlantic Monthly*, July, 1896.

forces are at work evolving truth and casting aside error; and, finally, that man's present position in this great work removes him from the place of a creation of the hour, and stamps him as the product of all time and the heir of all eternity.

The century upon the threshold of which we stand is lighted with jewels of hope in golden settings, and its atmosphere is filled with the sweet music of promise. The brightness of the one and the melody of the other is enhanced by the thought that no Macaulay-like prophet has conjured up the vision of a horde of wolf-like charlatans running riot among the fallen columns and dismantled arches of the Temple of Science, that mighty citadel so graphically described by our own Holmes as

The towering pride of twice a thousand years.

CLINICAL MEMORANDUM.

EXTERNAL URETHROTOMY IN A CHILD, AND OTHER CASES.[1]

BY FRANK C. HAMMOND, M.D.,
OF PHILADELPHIA, PA.;
SENIOR AND SURGICAL RESIDENT ST. JOSEPH'S HOSPITAL.

CASE I.—G. D., female, six years of age, was admitted to the ward, April 6, 1896. About four months prior while at play she fell and struck her left knee a violent blow. A week or two following the injury, slight swelling was noticed by the mother, in the neighborhood of the joint. On examination the knee of the affected side was found greatly swollen, almost three times the size of the sound side. The color of the skin surrounding the joint was the same as that of the remaining portion of the leg. On palpation it felt several degrees warmer than the sound joint. In comparison with the other leg, no atrophy was present either above or below the articulation. The child was able to stand on the leg, but unable to bend it at the knee. The patella was adherent, and the tissues surrounding the joint markedly resistant. Although no tubercular history could be obtained, there was some doubt in regard to the mother's physical condition, as there was an impairment of resonance over the apices of the lungs. The mother refused to bring a specimen of her sputum for bacteriological investigation, hence the presence or absence of tubercle bacilli could not be ascertained. However, everything pointed to a tubercular arthritis. The little sufferer was placed in bed, and extension applied by means of weights over the foot of the bed. Sand-bags were also applied, and the child was placed on a full diet of the hospital-diet list. On June 22d the mother was very anxious to take the little one home, and she was allowed to go. On that date the swelling had subsided to such a degree that the affected knee was very slightly larger than the sound one, the patella was freely movable, and she was able to bend the knee and walk with little difficulty. After the first two weeks in bed no pain was experienced on examining the joint.

CASE II.—April 8th, about eight A.M., J. C., six years of age, was brought to the hospital by his mother, who gave the following history: About one year ago the boy suffered from a severe attack of acute gastritis, and after this from an entero-colitis. Prior to and since this attack he has enjoyed very good health. The evening of the 6th he complained of sharp pains in the hypogastrium, which later on in the night became quite severe. The mother, thinking it was a similar attack to the one twelve months previous, administered Hoffmann's anodyne. This apparently relieved the child, for he complained of no pain till the following morning. During the night no urine was passed. The morning of the 7th the severe, sharp, stabbing pains returned, and occurred off and on during the day. The child was permitted to attend school, and on his return home in the afternoon he informed his parents that he had not urinated since early the evening previous. During the evening of the 7th, the pain increased, and the constant desire to pass urine manifested itself. The next morning, thirty-six hours after the attack began (and during this time no urine had been passed), he was taken to the family physician, who referred him to this hospital for operation. On examination I found the bladder greatly distended, pyriform, and with its fundus reaching as high as the umbilicus. The bladder seemed on the verge of rupturing. The slightest touch of the abdomen in this region was resented by the child, owing to the existing tenderness. The tongue and mouth were markedly dry, the skin was warm, relaxed, and covered with perspiration; pulse and respiration slightly accelerated. Temperature, taken sublingually, 100° F. A filiform catheter was introduced into the urethra, which met with an obstruction at its membranous position. Tapping on the obstruction with the catheter, a noise was produced, distinctly heard by those around, and a diagnosis of impacted stone was made. Following along the track of the urethra externally, the stone could be easily felt, and readily seized between the fingers. As is the custom, I intended sending for my chief, but fearing the bladder might rupture prior to his arrival, I decided to do an external urethrotomy at once. The child was chloroformed and placed in the lithotomy-position. The parts were scrubbed and everything prepared to do an antiseptic operation, as antisepsis, during and after the operation, has minimized the danger of laceration of the mucous membrane.

The stone was seized between the thumb and index-finger, and was cut down upon. The incision was made over the urethra, at the junction between the penis and the scrotum. The skin was incised, and the underlying cellular tissue separated with the handle of the knife. The urethra was opened directly over the stone, and owing to the edematous condition present, some little difficulty was experienced in removing the stone from its boggy bed. Upon its removal the urine failed to flow away. A metal catheter was then introduced through the meatus and penile urethra, but I was unable to pass it beyond the incised portion of the membranous urethra. This being unsuccessful, catheterization was then tried through the incision, endeavoring this way to enter the membranous urethra, and then enter the bladder.

[1] These cases occurred in the service of Robert B. Cruice, M.D.

This procedure, however, proved a failure. Then the first method was repeated; this proved successful. The major portion of the urine was allowed to escape, the catheter was permitted to remain, and the external end cut off about an inch from the meatus, and retained in position by means of silk and adhesive strips. The incision was closed by three silk sutures, which were removed on the sixth day with primum intestionem. About an hour after the operation the remaining urine was allowed to escape, and the bladder was washed out with a boric-acid solution. The catheter was removed at the end of ten days, and since then not the slightest inconvenience has been experienced on urination.

Since the operation bougies have been introduced from time to time, but no contraction of the urethra has been found. On the second day the temperature returned to normal, and remained so until the boy's discharge, April 24th. The stone was brittle, and a small piece chipped off during its removal. It was roughened, measured three-eighths of an inch in diameter, and was a uric-acid calculus.

CASE III.—J. H., male, aged twenty-five, electrician, was admitted to the house shortly after midnight. This man works in one of the power-houses near by, and while passing in front of the switch-board, through an imperfection, a flash occurred. As a result the face, neck, both arms and hands, and front part of chest were burned, the hair being singed off the head, eyebrows, and eyelids. There was no involvement of the cornea or conjunctiva. He was suffering a great deal of pain, though very little shock. He was completely enveloped in gauze, saturated with carron-oil, which had been applied by his fellow workmen. After being removed from the receiving-ward to the surgical ward, the above dressing was removed, and one of saturated solution of sodii bicarbonas instituted. After the expiration of thirty-six hours all sensation of heat had disappeared, and an antiseptic dressing consisting of a carbolic-acid solution was substituted. In the dispensary- and ward-work we have found carbolic acid to be the preferable dressing for burns and scalds. It not only acts as an antiseptic, but also relieves the burning sensation and pain. The temperature during the night and next day ranged along 102° F. Second day it fell to 99⅘° F., then gradually ascended, till on the fourth day it reached 102⅘° F., and remained so until the evening of the fifth day, when it gradually began to descend, and on the ninth day it had reached normal. Some superficial sloughing occurred on the neck, arms, and chest; none on the face. None of the complications such as duodenal ulcers and nephritic lesions, so common with such extensive burns of the body, were present. On the day of discharge, July 13th, the various surfaces had all healed, and the only contraction present was on the right half of the neck, the chin being drawn downward and to the right of the median line. The patient expects to return to the hospital sometime this fall for an operation to relieve this contraction. According to the statement of members of the staff, this was one of the worst cases of the kind ever admitted to this hospital.

MEDICAL PROGRESS.

Auto-intoxication from Chronic Constipation.—As the result of a careful study FERMI and CASCIANI (*Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten*, 1896, Nos. 22, 23, p. 869) have arrived at the conclusion that the symptoms associated with chronic constipation are attributable to a multiplicity of causes. Neither the mechanical theory, nor the nervous theory, nor the theory of auto-intoxication affords alone a sufficient explanation. The symptom-complex may result from auto-intoxication in consequence of the absorption of toxic substances generated in the gastro-intestinal tract; from auto-intoxication resulting from diminished or abolished excretion through the bowel of normal or pathologic substances, and especially through the reflex influence resulting from the mechanical or chemic irritation due to retarded intestinal activity.

THERAPEUTIC NOTES.

For Malarial Fever in Children.—

℞	Tinct. of *Eucalyptus globulus* } Alcohol }	aa	2 fluidrams
	Quinin hydrochlorate . .		½ dram
	Quinoidin		1 scruple
	Hydrochloric acid, sufficient to make a solution.		

Dose: From 20 to 40 drops five times a day.

—ZUCKERMANN, *Semaine Médicale*, 1896, No. 35.

Palliative Treatment of Carcinoma of the Uterus With Sodium Chlorate.—In the treatment of malignant disease of the uterus the employment of sodium chlorate is recommended both by internal administration and applied topically. For internal use the following formula may be employed:

℞	Sodium chlorate . . .	4 fluidrams
	Syrup of orange-flower . .	6 fluidrams
	Distilled water . . .	5 fluid ounces
	Mix.	

Dose: A tablespoonful or two from twice to four times a day.

As a local application a small amount of the following powder may be dusted upon the diseased surface:

℞	Sodium chlorate } Bismuth subnitrate }	aa . .	4 drams
	Iodoform		2 drams
	Mix.		

One may also employ tampons of sterilized gauze saturated with a mixture of

℞	Iodoform		1 part
	Sodium chlorate } Glycerin }	aa . . .	20 parts

If iodoform be badly borne and give rise to toxic symptoms, cotton impregnated with salol may be used, being first immersed in a twenty-per-cent. aqueous solution of sodium chlorate.

Under the influence of the foregoing treatment metrorrhagia and fetid discharge diminish, the pain lessens, the turgescence of the cervix subsides, ulceration disappears, appetite and digestion are restored, and the general state is improved.—*Semaine Médicale*, 1896, No. 35, p. 278.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

SATURDAY, NOVEMBER 28, 1896.

INFANTILE TUBERCULOSIS BY INGESTION.

TUBERCULOSIS of the intestine is exceptional in the first two years of life, as shown by the statistics of Weiderhofer, who, in 101 cases of intestinal tuberculosis in childhood, found only six under two years of age, and a percentage of eight for all cases of tuberculosis under two years, as opposed to twenty-eight per cent. for cases in children from two to fifteen years of age. Three sources of origin for intestinal tuberculosis are possible: (1) In acute miliary tuberculosis small, gray, semi-transparent granulations may be found upon the intestinal mucous membrane. These are hematogenous in origin. (2) In young children having chronic pulmonary tuberculosis with cavities the intestine may be infected from the swallowed expectoration. The lesion then assumes the common ulcerous form seen in adult consumptives. It is extremely rare under two years. (3) After the ingestion of tuberculous food, especially the milk of a tuberculous cow. In these cases there may be no lesion of the intestinal mucous membrane, the bacillus having traversed it to find a suitable soil for growth in the mesenteric glands. When lesion of the mucous membrane occurs it ordinarily assumes a special form—discrete without ulceration. This is characterized by submucous nodules the size of a pea, filled with gray, or cheesy, more or less softened material, and united by a delicate, fibrous covering, these nodules corresponding in position with the affected mesenteric glands.

Drs. Marfan and Apert in the *Revue Mensuelle des Maladies de l'Enfance*, June, 1896, consider the above subject, basing their remarks on a somewhat unusual example of tuberculous disease in a child, aged sixteen months. This child had been nourished only at the breast, with the exception of certain days, when, the mother being at work, cow's milk had been given. The family history showed healed tuberculous cervical adenitis in the mother. One of her nine children had died of tuberculous peritonitis, and another had coxalgia. At the age of nine months the patient had come under treatment for a suppurative adenitis of the neck, and at this time it was noticed that there were ulcerations upon the gums, covered by pultaceous and fetid exudate, which persisted despite treatment instituted at the time. At the age of thirteen months a diarrhea began, and persisted without amelioration till death, a few days after admission to the hospital. The autopsy revealed an enormous mass of tuberculous mesenteric glands, with tuberculous ulcerations of the colon, ileum, jejunum, and duodenum; the liver, spleen, heart, and kidneys were normal; a few small, recent, grayish granulations, with two small foci of broncho-pneumonia in the right base, indicated the degree to which the lungs were involved.

According to the authors the first focus of disease was the mouth and the ganglia of the neck; next the intestine. The slight pulmonary lesions were of recent origin. The source of the infection must be assigned to the milk of the mother or of the cow.

The importance of the subject in the early feeding of babies cannot be too urgently insisted upon. If the mother of the child is tuberculous, the first duty of the physician is to remove the child immediately from its mother's milk, and rear it preferably on the breast of a healthy wet-nurse, or if this is impracticable, upon sterilized milk of the cow. As pointed out in a recent editorial the principle of "ingestion tuberculosis" is practically recognized in Denmark in the rearing of cows, horses, and swine.

THE TREATMENT OF DIPHTHERIA WITH THE ANTITOXIN.

ADDITIONAL testimony is constantly accumulating to establish beyond doubt the utility of the

antitoxin in the treatment of diphtheria. A recent contribution can be found in the report made by Furth (*Münchener medicinische Wochenschrift*, 1896, No. 29, p. 669) of 150 cases thus treated at the medical and surgical clinics of the University of Freiburg. This report is supplementary to a previous report of 100 cases treated in the same way. Of the 150 cases diphtheria-bacilli were found in 123. In the remaining 27 the diagnosis was confirmed by subsequent tracheotomy; of these, besides, 13 terminated fatally, and were examined *post mortem*. Twelve cases in which diphtheria-bacilli were not found, were treated with the antitoxin, but they are not included in these statistics. In 34 of the 123 cases streptococci also were found, but the examinations were made twenty hours after inoculation—at a time thus unfavorable to the development of streptococci. In 5 children with laryngeal diphtheria, of whom 3 required tracheotomy and 2 died, diphtheria-bacilli were cultivated from the pharynx, although this was free from membrane, swelling, or redness. One of these children had also measles, so that the diagnosis was a matter of considerable significance. Of the 150 cases 122 were uncomplicated and 28 complicated. The complications included measles (16), scarlatina (5), measles and scarlatina (2), measles and typhoid fever (1), and tuberculosis (4). Among the 122 uncomplicated cases there were 12 deaths (9.8 per cent.); tracheotomy was required in 26 cases (21.3 per cent.), with 9 deaths (34.6 per cent.). Among the complicated cases there were 11 deaths (39 per cent.); tracheotomy was required in 9 cases (32 per cent.), with 6 deaths (66.6 per cent.). Of the whole number of 150 cases death occurred in 23 (15.3 per cent.).

Notwithstanding the coincidence of epidemics of measles and scarlet fever the mortality was lower than in any previous year. The proportion of cases requiring tracheotomy was also smaller, and the mortality among these also lower. Over and above the complications the disease itself was in many instances of unusual severity. While in former periods the mortality in early life had varied from 60 to 100 per cent., in the present collection of cases there were only 3 deaths among 19 children under two years of age, although 8 of these cases required tracheotomy. The dose of the antitoxin employed was larger than previously. Of the fatal cases 2 were septic, without involvement of the larynx. Both of these came under observation on the fourth day of the disease, and death took place in sixteen and sixty-eight hours, respectively. In 6 cases death resulted from descending croup; all required tracheotomy. In 2 cases death was due to diffuse bronchopneumonia, after the local process had terminated. Finally, in 2 of the cases, death resulted from paralysis of the heart on the sixth and forty-first days of observation, respectively.

BROOKLYN'S CHARITY HOSPITAL.

Commissioner Bergen of the New York State Board of Charities has recently filed in Albany a report on the Kings County Hospital. He presents in greater detail the disgraceful conditions existing in that institution, but otherwise only repeats facts which have already been pointed out in our editorial columns, October 3, 1896. The observations cited by Mr. Bergen were made more than six months ago, but from personal inspection we know that the conditions have not improved, and if possible are now even worse than he depicts them. This hospital is the largest in Kings county, and in number of inmates the third largest in the State. Within its doors are found all sorts and conditions of the afflicted poor, a large portion of whom would find more appropriate accommodations in almshouses, workhouses, homes for incurables, or inebriate asylums.

The immediate management is absolved from responsibility for the existing conditions because of the inexorable requirements of the law, which compel it to receive every applicant residing within the county, as well as State paupers, upon contract, and those suspected of insanity until examined by the physicians. It matters not what demands are made, no one of these can be rejected upon the excuse of a lack of room.

There results from this the fact that there is an average of more than twenty persons in each ward, originally designed to accommodate ten. A surgical ward provided with ten beds was made per force to accommodate twenty-four patients. Another had ten beds and thirty-three inmates. Nurses sleep in the wards with the patients, and in the entire hospital considerably over two hundred of the inmates sleep on mattresses thrown upon the floor.

During the past year relief was sought by diverting to building purposes $40,000 which had

been saved from the appropriation for current expenses, but through official indirection this sum remains unavailable. And thus suffering, filth, and criminal neglect make the daily record of Brooklyn's care of her helpless poor, while officials squabble over technicalities.

This incongruous horde of broken humanity, with afflictions differing less in distressing form and fatality than in pathological variety, herded like cattle beneath this single roof, presents a scene too repulsive for the eyes of this enlightened age. To the eternal shame of Brooklyn be it known that she is silently fostering this abuse. Why criticise the cruel Spaniard or fly in the face of the unfeeling Turk, while at our very doors such crimes are committed in the name of charity?

ECHOES AND NEWS.

The New York Hospital.—It is reported that Dr. William H. Draper has resigned his position as visiting physician to this hospital.

Dr. Moore Madden Honored.—The Royal University of Ireland has conferred the degree of Master of Obstetrics (M.A.O.) on Dr. Moore Madden, well known as the author of "Clinical Gynecology."

The Deborah Nursery.—The New York Board of Health has ordered the vacation of the Ladies' Deborah Nursery and Child's Protectory, unless proper medical attendance for the ophthalmic children there is provided.

Preliminary Examinations in Missouri.—How urgent has been the need of an entrance-examination in the Western medical schools is indicated by the results of a recent test. Of seventy-two candidates thirty failed.

Honor Conferred.—The Asiatic Society of Bengal at its last annual meeting elected Sir Joseph Lister and Professor Michael Foster honorary members to fill vacancies made by the deaths of Professor Huxley and M. Pasteur.

A New Turkish Bath.—The hot-sand bath in vogue among Mohammedans has been tried by Swiss physicians with good results in rheumatism, gout, and neuralgia. It is regarded as a potent sudorific which does not affect the heart.

The Epidemic of Beri-beri in Dublin.—There have been ninety-eight cases of beri-beri, with six deaths, to date, in the recent epidemic at the Richmond Asylum, Dublin. The epidemic is characterized by a tendency to frequent and sudden relapses.

The Harlem Dispensary.—The great increase in the number of poor patients applying to the Harlem Dispensary for treatment has necessitated its removal to larger premises at 108 East 128th street, which were formally opened November 23d.

A Meeting of Assistant Physicians of Hospitals for the Insane.—The fourth meeting of the Association of Assistant Physicians of Hospitals for the Insane will be held at the Eastern Michigan Asylum, Pontiac, Mich., on December 3 and 4, 1896.

Medical Electricians.—Drs. Milne Murray and Dawson Turner have been appointed, by the Medical Managers' Committee, medical electricians to the Edinburgh (Scotland) Royal Infirmary, where a very complete electrical plant has been established.

Formalin and Museum-specimens.—Several pathological specimens which had been preserved by formalin were exhibited at a recent meeting of the London Pathological Society. Though they had been preserved for several months, no change in their original color was observable.

Cancer Treated by the X-ray.—The *Lyon Médical* tells of the treatment of cancer of the stomach by the X-ray, and claims that it ameliorated the general condition and prolonged the patient's life for two weeks, absolutely suppressing the pain over the tumor and notably diminishing the volume.

The Journal of Nervous and Mental Disease.—The following are announced as editors of this journal for the coming year: Drs. Chas. L. Dana, F. X. Dercum, Philip Coombes Knapp, Chas. K. Mills, Jas. J. Putnam, B. Sachs, M. Allen Starr. Dr. Chas. Henry Brown will be managing editor.

Hughlings Jackson Lectureship.—The Neurological Society of London has announced its decision to establish a lectureship to be named in honor of Dr. Jackson, one of the founders and the first president of that body. At the earnest request of the Society, Dr. Jackson has consented to deliver the first lecture.

Brooklyn's Water-supply.—Mayor Wurster of Brooklyn urges that the question of the future water-supply for the city be settled before he retires from office and before the city becomes a part of the Greater New York. He has decided to hold public hearings on the subject, at which the matter can be freely discussed.

Life-insurance of Women.—Only eight or nine of the life-insurance companies insure women at the same rate as men. Further experience is now convincing these companies of the injustice of this discrimination. The mortality-rate among the female risks in one company did not rise above eighty per cent. of its anticipation.

The German Poliklinik.—On the 17th of December, an entertainment will be given at the Metropolitan Opera House under the management of Messrs. Daly, Frohman, Seidl, and others for the benefit of the New York German Poliklinik. This institution has quite outgrown its present quarters, and increased funds are needed.

The Uniform of Bellevue Hospital.—One hundred and twenty-five attachés of Bellevue Hospital appeared in uniform this week. The men are divided into five grades, each grade having a distinctive style of uniform. The

uniforms of four grades are of blue cloth, trimmed with red braid, while those of the fifth grade are of gray cloth.

An Elevator Accident.—One day last week an elevator-car in the American Tract Society Building, New York, became unmanageable and fell several stories. The man in charge, with commendable presence of mind, called upon the passengers to stand upon their toes, thus breaking the force of the concussion. One man fractured his patellæ. But the advice saved all the others from serious injury.

The Climate of England.—At the recent sanitary congress in London Mr. Dines said that it was satisfactory to find that the much-abused climate of England was superior to that of any of the colonies in which troops were kept, excepting Canada. Dealing with the Registrar-General's returns, the President came to the conclusion that a temperature below 60° F. was the most suitable for human life.

New York's Low Death-rate.—The number of deaths from all causes—566—for the week ending Saturday, December 21st, was remarkably low. It is the lowest death-rate that has been reported for any single week since the first week in December, 1889, when the deaths were also 566. No lower number of deaths has been reported since the first week in November, 1887, when there were 565 deaths.

Female Members of the Royal College of Surgeons.—The question of granting diplomas of the Royal College of Surgeons to women is exciting much interest in medical circles of England. The meeting of Fellows favored, but the Council vetoed the proposal, because the allied College of Physicians declined to concur, and because they believed that women are not physically fitted to undertake the major surgical operations.

A Directory of Nurses.—The first edition of a Trained Nurses' Directory by Miss Louise Longeway of New York has just made its appearance. It contains only the names of nurses who have graduated from schools giving a minimum course of two years in a hospital of over one hundred beds. In addition to this, a years' experience in private nursing, and the certificates of prominent physicians and surgeons are required.

The Blind and the X-ray.—From certain experiences in a dark room, Edison determined to try the effect of the ray on two blind men. Experiments were tried with different tubes, and the men said they could distinguish little points of light. The opportunity for embellishment which this afforded was not to be lost, and Mr. Edison was even reported as having said with the X-ray he could make the blind see. The *Sun* quotes him as much annoyed by the absurd statements that had been made.

The Paris Water-supply.—The French capital has already exhausted all the available water in its vicinity, and still the supply is very inadequate. Excluding a certain percentage of very questionable water taken from the Seine and the Ourcq Canal, the amount furnished each inhabitant *per diem* is only a little more than half what is provided in New York City. In order to meet the imperious demands of hygiene for a more liberal supply, Paris is now seriously considering a project of bringing water from Lake Geneva, at a cost of $100,000,000. This source is said to be unexcelled in purity.

The Proposed Infirmary at Harvard University.—For the last two years there has been agitation for the establishment of an infirmary at Harvard. The corporation is now ready to contribute toward buying a suitable site, and a tentative plan has been prepared by an architect. It is hoped that the remainder of the funds required will be raised by subscription. Meanwhile the *Harvard Graduates' Magazine* has proposed a plan by which the running expenses of the infirmary may be met by a fixed charge on the term-bill of each student, and medical attendance for poor students be supplied out of the general sum.

Beer-adulteration.—The New York State Board of Health has been requested to urge the enactment of a law requiring that only hops and malt shall be used in the manufacture of lager beer, and that its chemist shall analyze the different beers manufactured in the State and ascertain whether substitutes for hops are being used, particularly glucose, corn-meal, rice, sirup, and starch. The time during which the beer is stored will also, it is said, be regulated by law, owing to the notoriously injurious properties of beer only a few weeks old. There are 289 breweries in New York, producing annually 10,000,000 barrels of beer.

The New York Academy of Medicine.—At the annual meeting of the Academy, held November 20th, Dr. George R. Fowler of Brooklyn delivered an address entitled "The Evolution of the Surgery of the Twentieth Century" (see p. 602). Dr. Joseph Bryant, the president of the Academy, announced that most encouraging progress had been made in raising the endowment-fund of the library to $100,000. The original fund amounted to $50,000. During the past year $30,000 more has been added to this. In January the Academy will celebrate its semi-centennial anniversary in Carnegie Hall. The chief feature of this celebration will be an address by President Cleveland.

Resolutions on the Death of Dr. Burchard.—The Northwestern Medical and Surgical Society adopted the following resolutions in regard to Dr. Thos. H. Burchard: *Whereas*, It has pleased God to take away Dr. Thos. H. Burchard, distinguished by twenty years of active and faithful membership in the Northwestern Medical and Surgical Society of New York, and *Whereas*, Our hearts are touched with a great sorrow by the suddenness of his decease, therefore *Resolved*, That we desire to place on record an expression of our esteem of our late colleague, who had endeared himself to us by a long line of friendly and generous offices; that we desire to commemorate his devotion to the medical profession, exemplified in so high a degree by his many contributions to this and to other medical bodies, and by his acknowledged skill as a surgeon; and that we realize in the life of our friend the large equipment of mind and body essential to the success of a true physician.

Twelfth International Medical Congress.—The American National Committee of the Twelfth International Congress, which is to meet at Moscow, Russia, from August 19 to 26, 1897, consists, according to the directions of the General Committee at Moscow, of the following gentlemen: J. S. Billings, M.D., New York; Frank P. Foster, M.D., New York; S. Weir Mitchell, M.D., Philadelphia; Charles A. L. Reed, M.D., Cincinnati; George B. Shattuck, M.D., Boston; F. J. Shepherd, M.D., Montreal; George F. Shrady, M.D., New York; W. S. Thayer, M.D., Baltimore, and the chairman, A. Jacobi, M.D., 110 West Thirty-fourth street, New York. The chairman begs to invite the attention of the medical profession of the United States and Canada to the fact that the professional gentlemen in charge of the Congress are anxious to make it a success both from a scientific and a social point of view. Their difficulties are unusually grave, but it is not their fault that the Congress had to wait for governmental permission to meet in their country, or that a special ukase was required for the admission into Russia of Jewish medical men on equal terms with their Greek, Catholic, Protestant, Agnostic, and Mohammedan colleagues; or that the famous and meritorious Secretary-General was—it appears because of his liberalism—ousted both from his place and from his professorship. They should not be held responsible for the political semi-barbarism of the country in which they live. Their position in the world of science and their endeavor to make the Twelfth Congress equal to its most famous predecessors, will prove an incentive to American physicians to sustain, both by their presence and their contributions, the Russian committee.

The Loomis Sanitarium for Consumptives.—On Friday, November 20th, the buildings composing this sanitarium, which have recently been constructed near the town of Liberty, Sullivan county, N. Y., were dedicated. This sanitarium is a country branch, so to speak, of a small hospital in West Thirty-eighth street, New York City, and has been constructed for the purpose of carrying out the well-recognized principle in tuberculosis that if a patient in the early stages of consumption can obtain a few months' residence in a suitable climate under favorable hygienic surroundings, it is possible, in a certain proportion of cases, to arrest the disease. Only those are admitted who are in the early stage of consumption, and to whom a residence for a number of months in the sanitarium promises either a complete cure or such an improved condition that they can return to their homes and be able to carry on their work. It is a charity, pure and simple, intended for clerks, bookkeepers, self-supporting women, etc. There are no free beds, but the expense is only nominal, ranging from $5 to $7 per week. The atmosphere and climate in the high altitudes of Sullivan county resemble very closely those of the Adirondacks, and this sanitarium is run on exactly the same basis as the sanitarium at Saranac Lake. The ground contains 150 acres among the mountains, three miles from Liberty, and 2200 feet above the sea. The sanitarium has been open since June last, and the demand for accommodation has been so great as to necessitate the use of wards originally intended for emergency cases. The present capacity is thirty-one beds. Patients are admitted after examination by either Dr. Loomis or Dr. Quimby of New York City, or by Dr. J. E. Stubbert, at the sanitarium.

Semi-centennial of the American Medical Association.—In view of the fact that the next meeting, which is to be held in Philadelphia, June 1–4, 1897, will be the semi-centennial gathering, and that it will occur in a great medical center, and near the other great cities of the Eastern coast, the Committee of Arrangements for this meeting have already made provision for the accommodation and entertainment of the delegates by the engagement of the Academy of Music, Horticultural Hall, the South Broad Street Theater, and the large meeting-rooms in the Hotel Walton and Hotel Stenton. As these large buildings are all within a short distance of the great railroad depots in the center of the city, and are all situated within one block on both sides of Broad street, every department of the meeting will be conveniently arranged. At the last meeting of the Association it was voted to devote the first evening of the meeting, Tuesday, June 1st, to dinners of the various sections. The officers of the sections desiring to give such a dinner will please communicate with Dr. G. E. de Schweinitz, Chairman of the Sub-committee on Accommodation, 1401 Locust street, as early as possible in order that dining-rooms may be engaged or other entertainment provided. As it is expected that fully three thousand physicians will be present, the committee suggests that applications for accommodations be made as early as possible. It is hoped that every member of the association will make a special effort to attend. Further circulars of information will be issued by the committee from time to time. Individuals and firms desiring space for exhibition in the Exhibition Hall, which will be in the same block as the various meeting-halls, will please apply promptly to the Chairman of the Sub-committee on Exhibits, Dr. Edward Jackson, 1633 Locust street, Philadelphia.

The Execution of Eight Medical Students.—The Cuban Professional Club of New York commemorated on November 27th the twenty-fifth anniversary of the shooting of eight medical students by the Spanish volunteers in Havana. At 10 A.M. a requiem mass was celebrated at the Church of St. Leo. At eight o'clock in the evening a meeting was held in Chickering Hall. The shooting of the Havana medical students was an atrocious example of Spanish barbarity in Cuba. On November 22, 1871, the class went as usual to the San Dionisio Hospital, and learning that the teacher was absent, decided to spend their unexpected recess in the adjoining cemetery. On the 25th the boys were surprised to see the civil Governor of Havana appear in the class-room. In angry words he said he had come to find out who was the author of the "crime," and added: "One of you has desecrated the tomb of Don Gonzalo Castanon. If you do not say who did it, you will all be held responsible for the crime." All the students were taken to jail, excepting a Spaniard, who, the Governor said, could not have done such an infamy. Don Gonzalo Castanon was a Spanish journalist, who, after having

abused the Cubans in a most indecent way and caused many to be put to death, was killed by a Cuban in a duel at Key West. Without any investigation, the volunteers demanded the lives of the medical students, and, although it would have been easy to go to the cemetery and see that the tomb was untouched, the authorities submitted to the volunteers' demands and the students were "court-martialed." The council sentenced to death eight of the forty-three students. Thirty-two were condemned to hard labor. One of them, Dr. Ricardo Gaston, is now president of the club Oscar Primelles, under whose auspices the anniversary is commemorated. The remaining student, Octavio Smith, was acquitted. He was an American citizen. On November 27th the eight students were shot.

Obituary. — Sir Benjamin Ward Richardson, M.D., F.R.S., died November 21st. He was born in 1828, was made an honorary member of the Philosophical Society of America in 1862, and was a member of a number of other prominent societies. He has been president of the Medical Society of London, and was thirty-two times president of the St. Andrew's Medical Graduates' Association. He succeeded Lord Jervis Woode in 1869 as assessor for the general council in the University Court of St. Andrews, and held that office for nearly sixteen years. At the Social Science Congress at Brighton in October, 1895, Dr. Richardson read a paper in which he gave a sketch of an imaginary "model city of health," to be called Hygeia, which caused much discussion. Dr. Richardson took an active interest in the development of bicycling, and was president of the Society of Cyclists. He was knighted in 1893.—Dr. Luis F. Sass died in New York, November 19th. He was born in Havana, seventy-six years ago, and educated in Paris, and had practised in New York for thirty years. He was the inventor of the Sass apparatus for spraying the throat.—Dr. Philip C. Williams of Baltimore died November 22d, at his home in that city. He was born in Winchester, Va., in 1828. At various times he was president of the Medical and Chirurgical Faculty of Maryland, the Baltimore Medical Association, the Clinical Society of Baltimore, and the Pathological Society of Baltimore.

CORRESPONDENCE.

SECOND PAN-AMERICAN MEDICAL CONGRESS.

Held in the City of Mexico, November 16, 17, 18, and 19, 1896.

[From our Special Correspondent.]

HOTEL DEL JARDIN,
IA CALLE DE LA INDEPENDENCIA,
City of Mexico, November 18, 1896.

AS I sit in my room in this curious old convent-hotel this beautiful November day, with the soft southern sunlight streaming in at the wide-open window, and with visions before my eyes of austerely clad nuns, sedately walking between the box-hedges of the quaint old garden, I am mindful of Joaquin Miller's lines to Montezuma's ancient capital:

> This city rests in God's right hand,
> Its sapphire wall is Heaven's wall;
> Where God has done so much for man
> Shall man do naught for man at all?

and the last line is of special significance in connection with the object of my visit—attendance upon the Second Pan-American Medical Congress.

Popocatepetl and Ixtaccihuatl rear their snow-capped summits in sight against the clear tropical sky, and the oddly sounding street cries come faintly to my ears as I train my pen to its duty, vastly preferring as I do to allow my thoughts to wander to the ancient glories of Tenochtitlan, to the valorous deeds of its hero, Cuauhtemoc, the last of the Aztecs, and to the ruin wrought by that prince of adventurers, Cortes; but *duos qui sequitur lepores, neutrum capit*, and I therefore take warning.

The first instalment of delegates arrived on Friday evening last, and was immediately taken possession of by a committee, the members of which extended a hearty greeting and housed them pleasantly and comfortably in quarters previously provided. The wants of the ladies in the party were looked after by a special committee of ladies, and every effort was made to emphasize the sincerity of the welcome. Others arrived during the two following days, and until the opening of the Congress the time was delightfully spent in sight-seeing. Parties were organized to visit the Castle of Chapultepec, the Monte de Piedad, the famed Shrine of Our Lady of Guadalupe, the Floating Gardens, the Cathedral, and the National Museum, while on Sunday, at noon, everybody by common consent went to watch and criticize the promenaders in the famed Alameda.

Many of the delegates drove out to San Cosme, Calzade San Rafael, to inspect the American Hospital, founded in 1886 by the American Benevolent Society, with which Dr. W. Mallet-Prevost was so prominently connected. Dr. Prevost was graduated from the medical department of the University of Pennsylvania with the class of 1887, and was universally beloved by all who came in contact with him. He died from heart-disease two years ago.

The formal opening of the Congress took place at the Teatro Nacional on the evening of Monday, November 16th. This theater, the largest in Mexico, contains five galleries, and accommodates fully three thousand persons, and some idea may be gained of the interest manifested in the proceedings when I say that it was packed to the doors, no inconsiderable portion of the audience being composed of ladies.

The meeting opened with the report of the Secretary-General of the Congress, Dr. Eduardo Licéaga. He dwelt at some length on the successful efforts of Dr. William Pepper of Philadelphia, and Dr. Charles A. L. Reed of Cincinnati, toward the holding of the first Pan-American Congress in Washington in 1893, and of the hearty coöperation of President Diaz and the members of the Mexican Government in the endeavors of the Mexican Medical Society, to make the present meeting a success. He felt that the Mexican members of the Congress had especial cause for self-congratulation at the heartiness with which their invitation had been accepted, as special

delegates were in attendance from several of the States of the United States, and from most of the countries to which the invitation had been extended, including Canada, Guatemala, Nicaragua, San Salvador, Costa Rica, Honduras, Venezuela, Ecuador, Cuba, Uruguay, and Hayti.

In response to a notification sent out earlier in the year by the secretaries of the several committees, he was able to announce that nearly three hundred papers would be read before the different sections of the Congress during the present meeting. The Secretary-General closed his address by extending assurances of a warm welcome to all the visitors whom it was the honor of the President of Mexico and the Mexican medical profession to entertain, and expressed the hope that the happy relations existing between all Pan-American countries would be made stronger, if possible, by the efforts of their representatives joined together in the common cause of humanity.

Dr. Licéaga's remarks were greeted with long-continued and hearty applause, and he was followed by the President of the Congress, Dr. Manuel Carmona of Valle.

Dr. Carmona also referred to the previous Congress, and welcomed the delegates. He then read an exceedingly interesting paper on the history of medicine and of medical education in Mexico from the time of Cortes to the present day. He said that the first chair of medicine at the University was established in 1578, one professor teaching all of the branches, the course lasting four years. From this time on the advance was very gradual, and it was not until 1768 that the Royal College of Surgeons, with four chairs, was created, and dentists, bone-setters, blood-letters, and midwives graduated. After many vicissitudes, owing to political changes in the country, the name of the medical school, in 1842, was changed to "The National School of Medicine," and in 1854 was transferred to the old Inquisition Building in the Plaza de Santo Domingo, where it still remains. At present there are thirty-six professors connected with the school, and the average attendance of students is over three hundred. The school has a library of three thousand volumes, a fine amphitheater, cabinets of natural science and chemistry, and an observatory, and is in a very flourishing condition. The requirements for admission to the school are especially strict, as no matriculant is accepted who does not possess the degree of bachelor of philosophy. The course embraces a period of five years.

Dr. Carmona then spoke of the advances that have been made during recent years in bacteriological methods, and insisted that a new classification of disease was necessary, hoping that a distinct advance in this respect might result from the present meeting. He also referred to the frequent performance of unjustifiable surgical operations, and to the constantly increasing habit of prescribing proprietary medicines.

The next address was delivered by Dr. William Pepper, who was President of the First Pan-American Medical Congress, held in Washington. He spoke in most complimentary terms of the position Mexico has gained for herself in the van of medical progress, and expressed the hope that frequent medical reunions would take place in the future between the representatives of the two countries. He referred to the discoveries of Pasteur, of Behring, and of Kitasato along bacteriological lines, and paid a warm tribute to the discoverer of the Röntgen rays, in the latter connection relating the result of some experiments recently conducted with a specially designed tube, whereby he had been enabled to see distinctly the pulsation of the human heart.

Señor Don José Gamboa then read a paper on "International Sanitary Legislation," passing in review many interesting historical facts, and ending with a suggestion to establish permanent committees in each of the capitals of the Pan-American States, to deal with all questions of quarantine and hygiene. He believed that this would make possible the adoption by all the States of uniform laws governing sanitation.

Much interest had been manifested by all the northern delegates in the personality of General Porfirio Diaz, the President, or dictator, of the Mexican Republic, and when he stepped forward to close the evening's session, he was greeted with long-continued cheers. He spoke briefly in welcome of the visiting physicians and their wives, and stated that he had every reason to hope that the results of the Congress would confer lasting benefits upon the people of the New World.

Several receptions in honor of the visitors had been arranged for the evening, and at the conclusion of the meeting these were very generally enjoyed. The Jockey Club, that most aristocratic of Mexican organizations, which is housed in the grand Casa de los Azulejos, in the Avenida Oriente 4, the Casino Nacional, and the Anglo-American Club were each and all thrown open in the most truly hospitable fashion. Pulque, mescal, and tequila, those curious products of the century-plant, and aguardiente (sugar-cane brandy) were sampled by the curious, and the vinous products of other lands, too, were not neglected.

Tuesday, the second day of the Congress, opened with the reading of a paper by Dr. Juan Santos Fernandez of Havana, on "Yellow Fever as an Obstacle to Civilization." He claimed that to the prevalence of this disease was attributable the fact that the Spanish-American countries had been backward in development as compared with the United States. Immigration from European countries had been greatly restricted on this account, and it had been thought up to the present time that there was no remedy. He insisted that by enforcing strict isolation upon those attacked by the scourge, the disease could be effectually stamped out. He had great faith in the series of experiments that were being made with a view to conferring immunity from the disease, and trusted that before many months the desired goal would be reached.

Dr. E. P. La Chapelle of Montreal next addressed the meeting on "The Subject of Bacteriology, Hygiene, and Medicine." He paid a deserved tribute to the labors of Pasteur, and said that hygiene was but the perfected prophylaxis aimed at in all of the scientist's researches. It had now reached the plane of an exact science, and was founded upon the principles of disinfection and isolation. Upon it is based the theory and practice of modern medicine. The speaker referred to the mortality of child-

hood as influenced by proper hygiene of the alimentary canal, and to the carriage of the germs of typhoid fever and of cholera by water, which could easily be prevented by the employment of hygienic precautions. The careful study of this branch of medicine was becoming universal, and he hoped that the laity would soon arrive at the point where a complete understanding of its importance would render the enforcement of sanitary laws an easy matter.

(To be continued.)

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON PEDIATRICS.

Stated Meeting November 12, 1896.

WALTER LESTER CARR, M.D., Chairman.

LE ROY W. HUBBARD, M.D., exhibited a case of

CLUBFOOT, WITH ABSENCE OF TOES AND FINGERS, AND WITH CONSTRICTION-BANDS OF LEG AND FINGER,

and stated his belief that the sulcus around the right leg had the same origin as the other formations—*i. e.*, from pressure of an amniotic band.

THE CHAIRMAN remarked that it was not usual for the membranes to produce a linear constriction.

J. P. WEST, M.D., of Belair, Ohio, read a paper on

AN EPIDEMIC OF GLANDULAR FEVER,

which had occurred in his vicinity. Altogether, ninety-six cases had occurred in forty-three different families. None of the cases had developed during the summer months. The youngest child who contracted the disease was seven months old, and the oldest, thirteen years. The disease usually lasted a little over two weeks, but the active symptoms subsided for the most part after the first week. As the illness commonly terminated by a critical discharge, calomel was given in a few instances with the hope of hastening the crisis. This, however, proved a disappointment, for not only was the crisis not hastened, but the calomel produced marked prostration. In eighty-seven of the cases the liver was enlarged, and in fifty-three, there was enlargement of the spleen. The older children complained of choking sensations. The glandular swelling appeared smooth on inspection, but palpation would reveal the individual glands. As a rule, the enlargement began on the left side, and subsequently involved the right side. The period of incubation was apparently about a week. During this epidemic no cases of mumps occurred, and fifty-seven of the children had mumps either previously or subsequent to the epidemic of glandular fever. Apparently the source of the poison in glandular fever was not always the same.

DR. AUGUST SEIBERT said that he had seen about twenty-four cases during the past five years, only one of which had proved fatal. In this case, shortly after the right side had become involved in the swelling, the child became cyanotic, and died, evidently as a result of compression of the pneumogastric nerve. In one case, to which the speaker referred somewhat in detail, a diagnosis of meningitis had been made before he had seen the child, because of the opisthotonos, headache, and fever. In this case, there was an evening rise of temperature to 104° or over for nearly four weeks, and the temperature was not in the least controlled by the administration of quinin. As there was also a splenic enlargement, malaria could be fairly excluded. In making the diagnosis, it should be born in mind that there is no sore throat or tonsillitis; that the disease is usually unilateral at first, and that there is never any edema of the surrounding tissue, or suppuration of the lymphatic glands.

DR. HENRY KOPLIK said that although he had seen a large number of cases of lymphatic enlargement, he had never met with a case which seemed to him to answer the description of glandular fever, as originally given by Pfeiffer. The term was a vague one, and was not especially descriptive, although, perhaps, no better term could be offered in the present state of our knowledge. He was inclined to think that the infection of the lymph-nodes had its origin in the gut, and the absence of suppuration would indicate that it was not pyemic.

DR. FLOYD M. CRANDALL said that while glandular fever was certainly not of common occurrence, the description of it left little doubt of its title to be considered as an independent disease.

DR. ROWLAND G. FREEMAN said that the name "glandular fever" seemed to him particularly unfortunate, since it was the lymph-nodes that were involved.

J. LEWIS SMITH, M.D., read a paper[1] on

THE MODE OF EXAMINING SICK CHILDREN SO AS TO PROMOTE GREATER ACCURACY IN DIAGNOSIS.

DR. JOSEPH E. WINTERS said that success in the diagnosis of children's diseases depended not so much on skill, as upon the time, patience, and care bestowed by the physician on these cases. In his opinion it was not more difficult to make a diagnosis in children than in adults, because in the former we listen to the voice of nature rather than to the deceptive descriptions given by adults of the subjective phenomena. The less attention given to these subjective phenomena, and the more to the objective signs, the more accurate would be the diagnosis. The necessity of giving plenty of time to the examination of sick children had been well illustrated by Dr. Smith in his description of the sudden changes in temperature that sometimes followed slight emotion. It was a common, yet very reprehensible, practice, rashly to prescribe the new antipyretics for these cases of ephemeral fever in children. A few years ago he believed more deaths had been caused from the needless use of such drugs than from the pneumonias in which they were given.

DR. CRANDALL divided the children met with in practice into three classes, *viz.*: (1) the good children; (2) the timid children, and (3) the ugly children. It was easy to make the diagnosis in the good children, except among some of the older ones, who rather enjoyed the examination, and who were apt to mislead the physician if he happened to be so indiscreet as to ask leading questions. It would require much tact and patience to

[1] This will appear in an early number of the MEDICAL NEWS.

get along with the timid children. The children of the third class could be more easily managed by a quick and firm manner, than by wasting time in humoring them, only in the end to find it necessary to control them with a firm hand. As it was often impossible to make the examination when the child was quiet, it was essential that the physician should train himself to make his diagnosis even though the child was crying. It should be made a rule of practice to examine carefully not only the throat, but the whole body-surface. Those who believed that children were free from the deceitful practices of their elders would be led into serious error by some nervous and hysterical children.

DR. LOUIS FISCHER thought it should be an easy matter to differentiate between malaria and typhoid fever in children by examining the blood for the plasmodium of malaria. He thought more skill was required in examining a child than an adult.

DR. J. MILTON MABBOTT said that in view of what had been said about elevation of temperature being produced by fright, it would be well in some instances where a physician was called in to see a very nervous child, to make two or three visits of short duration rather than one prolonged visit.

DR. WILLIAM L. STOWELL recommended that in examining the throat of a refractory child, the physician should grasp the child by the back of the neck, and steady the head between this hand and the one holding the tongue-depressor. In collecting the urine of children for examination, the best plan was to use a very small silver catheter; for squeezing the urine out of the diaper or out of a sponge was entirely too crude a method.

THE CHAIRMAN emphasized the fact that many sudden and sharp fevers, as well as apparently urgent symptoms in children were often due solely to derangement of the alimentary tract.

DR. SMITH, in closing the discussion, said that he would suggest that in cases of diphtheria the physician should stand behind his patient while examining the throat, as in this way there was no chance of some of the secretions being coughed into his face. A neglect of this precaution in one instance that had come under his notice had resulted in the physician carrying home diphtheritic membrane on his beard, and giving the disease in a fatal form to one of his own children.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

The Ninth Annual Meeting, held in Nashville, Tenn., November 10, 11, and 12, 1896.

(Concluded.)

FIRST DAY—AFTERNOON SESSION.

JOHN T. WILSON, M.D., of Sherman, Tex., read a paper entitled

MENTAL COMPLICATIONS FOLLOWING SURGICAL OPERATIONS.

While surgical operations are sometimes the cause of serious mental disturbance, they sometimes cure these disturbances, especially is this the case with some melancholiacs. The question may very properly be asked, why should a surgical operation produce an attack of insanity? This can no more be answered in every case, satisfactorily, than can the question, why some persons become insane from the many other causes to which it is attributed, for in most cases these mental complications are a surprise, and no good reason can be given why they should follow. In others, however, a logical explanation might be had. If the patient is a high-strung, nervous individual, easily excited, unable to bear pain, the great and increasing dread of the anesthetic, the operation, or both, will so affect him that he will lose control of the will-power. In many of these cases, probably a majority, there is an hereditary taint or a strong neurotic tendency.

The author quoted Mairet, who thinks (1) that it is in those individuals who are predisposed by heredity or other grave causes—alcoholism, infectious diseases, etc.—that surgical operations give rise to insanity. (2) In the constituent elements of an operation that might act on the brain were two most important ones, namely, the anesthetic and the degree of surgical traumatism, with its after-effects, of which disturbed nutrition plays a very important part. (3) When predisposition, also, is considerable, the anesthetic alone may produce insanity, or it may result even after minor operations. It is, of course, necessary to take into consideration the mental state of the patient prior to the operation, especially in those graver ones where questions of life or death are frequently involved.

DR. E. S. LEWIS of New Orleans related the case of a woman, forty years of age, very hysterical, upon whom he had operated for laceration of the perineum. During convalescence the hysterical manifestations increased, and were associated with delusions. She was transferred to an insane asylum, and after a thorough examination by the physician in charge, an unfavorable prognosis was given. The family history showed traces of insanity.

In another case, a woman sixty years of age, he removed a very large adherent ovarian tumor. The operation was attended with considerable shock. For a few days subsequently the patient did well; had no fever during convalescence, but she later became perfectly insane. He had also seen after operations cases of temporary insanity which had passed off in a few months.

DR. W. E. PARKER of New Orleans had seen two or three cases of insanity following surgical operations, but had never been able to trace any history of insanity in the family. The insanity occurred in alcoholic cases. Two of the men either took morphin or cocain. In the management of such cases the particular drug, to which the patient was addicted, should still be continued in very small doses, being cut off gradually, not suddenly, as great prostration often follows the interdiction of a habit that has continued for a number of years.

DR. R. B. RHETT of Charleston, S. C., had met with two cases of mental aberration which followed the removal of the breast for cancer. A third case occurred in a young woman who had had puerperal insanity prior to operation. In two instances the insanity lasted for three days, in the other three weeks.

DR. A. M. CARTLEDGE of Louisville had only encountered what he considers pure post-operative insanity in two cases. One patient who had been in an insane asylum four years had developed a pus-tube. Just before operation the patient seemed perfectly rational, but on the third day thereafter a violent mania developed, which terminated fatally. The other case of insanity occurred in an unmarried woman, thirty-eight years old, from whom he had removed an ovarian cyst.

DR. JOHN D. S. DAVIS had encountered four cases. In one case—a young man—there was no history of insanity, but an analysis of the urine showed a great many casts and a slight trace of albumin before operation. Operative interference was followed by acute mania, which lasted seven days, and the patient recovered.

DR. JOSEPH TABOR JOHNSTON said that, in talking with Drs. Kelly and Noble, he learned that the latter had seen eight cases of insanity following perineal operations.

DR. WILSON had seen a number of cases of various forms of insanity following surgical operation, but does not think the disease occurs more frequently after operations upon the perineum and genitalia than any other part of the body. He does not think the physician is any more responsible for the death of a patient from insanity following an operation than he is for death following any other operation. He had never heard of a suit for malpractice being brought against a practitioner for a case of mental derangement from a surgical operation.

GEORGE BEN JOHNSTON, M.D., of Richmond, Va., followed with a paper on

SPLITTING THE CAPSULE FOR THE RELIEF OF NEPHRALGIA.

He drew the following conclusions:

(1) Nephralgia is not always associated with a demonstrable lesion. (2) When other evidences of kidney-disease are wanting, the pain is due to too tight a capsule. (3) Nephralgia may, and frequently does, simulate symptoms of gross tissue-changes or mechanical irritants. (4) Where severe and persistent pain in the kidney exists without other evidences of renal disease, exploratory operation is indicated. (5) When inspection, palpation, and needle-puncture fail to disclose a condition sufficient to account for the pain, the capsule should be freely opened.

J. WESLEY BOVEE, M.D., of Washington, D. C., read a paper on

URETERO-URETERAL ANASTOMOSIS

and reported an interesting case. He drew the following conclusions:

(1) Uretero-ureteral anastomosis is a perfectly feasible procedure. (2) Uretero-ureteral anastomosis, whenever possible, is far preferable to any other form of ureteral grafting, to nephrectomy, and to ligation of the ureter. (3) It should be done preferably by lateral implantation or by oblique end-to-end anastomosis, though the transverse end-to-end, or the end-in-end methods may be safely employed. (4) That constrictions of the caliber of the ureter do not usually follow attempts at suturing in closure of complete transverse section of the duct. (5) That nephrectomy for transverse injuries of the ureter *per se* is an unjustifiable operation. (6) That simple ligation of the ureter to produce extinction of the function of the kidney is too uncertain to justify its practice. (7) That drainage is not necessary if the wound be perfectly closed and the tissues throughout are aseptic.

DR. HOWARD A. KELLY said that every abdominal surgeon should be familiar with uretero-cystotomy or uretero-ureteral anastomosis, because in doing abdominal operations the surgeon was liable at any time to injure the ureter, when he would be confronted with the necessity of doing something to repair it. Dr. Kelly then pointed out the various ways in which the ureter might be cut during operations, and described the method he pursues in repairing such injuries.

DR. CHARLES P. NOBLE cited a case of neglected extra-uterine pregnancy complicated with an intraligamentous ovarian tumor. In operating, the intestines were apparently adherent over a mass of blood, and a large fleshy adhesion ran up on it. To save time, this was clamped, cut through, and the pelvis cleaned out. A hysterectomy was also necessary, as the anatomical landmarks were obliterated on both sides of the pelvis and the broad ligaments did not come down in the usual way. When the operation was completed, the patient was in collapse, and it was found that what was supposed to have been a fleshy adhesion was really the ureter and thickened peritoneum. The ureter was cut off almost up to the kidney itself. The lower part of the ureter was taken out with the mass of blood, there being only the upper three or four inches of the ureter left. Had any attempt been made to prolong the operation with the patient in collapse, death would have resulted. Although the ureter was short, it was dragged up into the upper end of the abdominal incision. It was impossible to do a uretero-ureteral anastomosis, or to switch the ureter into the bladder. Dr. Noble removed the kidney, therefore, and the patient recovered.

HENRY D. FRY, M.D., of Washington, D. C., read a paper on

PREGNANCY AND LABOR COMPLICATED BY FIBROID TUMORS OF THE UTERUS.

He advanced two propositions. (1) That the production of abortion is unjustifiable. (2) That labors presenting serious difficulty to delivery are best treated by abdominal section and removal of the child and tumor. This, while saving the life of many infants, will also diminish the maternal mortality.

Dr. A. J. COLEY of Alexander City, Ala., reported a case of cyst on the right side with a left uterine tumor, which was firmly fixed in the pelvis and complicated pregnancy. As pregnancy and labor advanced, the tumor was pushed above the brim of the pelvis, the woman was subsequently delivered naturally of a child, and is now attending to her household affairs. Dr. Coley counsels against operative interference in many of these cases.

DR. R. R. KIME of Atlanta encountered a case some two years ago, in a debilitated patient, with evidence of infection before labor. In introducing the hand a tumor was felt in the posterior uterine segment, crowding the cervix apparently above the symphysis pubis. By

waiting and placing the patient in the exaggerated Sims' position, and elevating the growth, delivery of the child was effected.

DR. HOWARD A. KELLY agreed with the conclusions of the essayist. There was a tendency on the part of the profession to interfere too much in cases of pregnancy complicated by fibroid tumors of the uterus. He had been called in consultation to see a number of such cases, but the indications were not such in some of them as to warrant the induction of premature labor. In many instances a consultation had been the means of postponing operative interference. Fibroid tumors in the upper part of the uterine body, unless large and multiple, were comparatively unimportant. If situated in the lower part of the uterus, as pregnancy advances, they should be pushed up, if possible, in order that labor may proceed naturally. On three occasions he had opened the abdomen, and had done a myomectomy for tumors complicating pregnancy, the woman subsequently going to full term, and being delivered normally.

DR. W. D. HAGGARD, SR., of Nashville mentioned a case of uterine fibroid complicating pregnancy, which came under his observation a few years ago. Hysterectomy was advised by the consultants, but not resorted to. The woman was subsequently delivered of a child, and the tumor six months later had entirely disappeared. Dr. Haggard reported a similar case.

DR. JAMES A. GOGGANS of Alexander City, Ala., had observed, during the last twenty years, a number of cases of pregnancy complicated by uterine tumors. He had seen the case referred to by Dr. Coley. He thinks it is unwise to resort to hysterectomy in a great many cases, believing that the tumors can be pushed up and delivery effected without surgical interference.

DR. JAMES MCFADDEN GASTON cited a case of dermoid tumor which complicated pregnancy. The obstruction was so great that it was utterly impracticable to undertake to deliver the woman by forceps, and it was concluded to lessen the obstruction by aspirating the tumor. This was done, and a little more than one quart of grumous material was drawn off, after which the woman was delivered with forceps of a dead child. Dr. Gaston believes that the woman will have to be subjected to a radical operation for the removal of the dermoid before perfect relief is afforded.

DR. GEORGE A. BAXTER referred to the danger of *post-partum* hemorrhage in cases of fibroids complicating pregnancy. The fibroid tumor interfered with uterine contraction, and consequently rendered it difficult to arrest hemorrhage.

DR. E. S. LEWIS said that during an experience extending over thirty-four years he had never seen a fibroid tumor which justified interference before labor; that is, a fibroid occupying the lower segment of the uterus and impinging upon the pelvic cavity. Within the past year he has delivered two women having large fibroids. In one case when pregnancy supervened, after suspension of menstruation for two months, he was unable for several months to determine the existence of pregnancy. The uterus then reached above the umbilicus, but the woman was pregnant, and was delivered at full term with forceps, and with no extraordinary difficulty. The other woman had an abdominal tumor the size of a six months' fetus. Although she had been married a number of years, she was about forty when she became pregnant. The tumor occupied the upper portion of the body of the uterus, but she was delivered without the use of instruments. He could conceive that, in a case of fibroid situated in the broad ligaments, or occupying the lower segment of the uterus, seriously impinging upon the cavity of the uterus, hysterectomy would be inevitable, but it has been his fortune to escape such cases.

DR. FRY, in closing, was glad to note that the general trend of the discussion was favorable to conservative work in the treatment of pregnancy, complicated by fibroid tumors of the uterus, and of permitting women to go to full term and trying to deliver them naturally. Some of the cases in the paper, which he did not read, exemplified the wonderful resources of nature in overcoming uterine obstructions. *Post-partum* hemorrhage was one of the serious complications of labor under these circumstances, and was common. If the placenta was attached to the fibroid tumor, hemorrhage was free. If it is found necessary to operate, Cæsarean section ought not to be resorted to, as the mortality following such a procedure was as high as eighty-four per cent. The best thing to do is to resort to hysterectomy.

SECOND DAY—MORNING SESSION.

R. R. KIME, M.D., of Atlanta, read a paper entitled

UTERINE DRAINAGE AS A FACTOR IN THE PREVENTION AND RELIEF OF PELVIC INFLAMMATION,

in which he drew the following conclusions:

(1) A uterine tampon is not a true drain, and even obstructs drainage in many cases. (2) Capillary drainage is secured by carrying a strip of gauze up into the uterine cavity, not packing it, and then it drains for a few hours only. (3) Gauze cannot even act as a capillary drain when either end of the center is constricted, or when coated with mucus. (4) Gauze, when saturated with serum, unless it contains an antiseptic, forms a hotbed for germ-development. (5) Never tampon the uterus in puerperal septic infection, except to check hemorrhage. (6) The good effect of a gauze-tampon in cases of endometritis, and after abortion, is not due to drainage, but to its effects as a tampon—*i. e.*, checking hemorrhage, stimulating uterine contractions, prolonging medication of the endometrium, and acting as a surgical dressing. (7) The uterine drainage-tube is the most essential factor in the treatment of puerperal infection, and affords the best method of securing drainage when demanded in other diseased conditions of the uterus. (8) It will save more lives, relieve and prevent more complications, than any other factor at our command.

W. E. PARKER, M.D., of New Orleans read a paper on

GUNSHOT WOUNDS OF THE ABDOMEN,

and reported thirteen cases, with six recoveries. He believed seventy-five per cent. of cases of wounds of the small intestine would recover if the cases were seen early,

the prognosis being better in this class of cases than in any other. He advised an early and rapid operation in all cases.

The diagnosis is generally easy, but when in doubt, he advised enlarging the wound or probing. In doubtful cases, he was inclined to attach much symptomatic importance to pain referred to the umbilicus. He stated that he had never seen a case where this symptom was not present. There is frequently but little shock when grave symptoms are present. Senn's gas-test was not used in any of these cases, and he spoke of it as being unnecessary in at least a majority of cases, uncertain in the hands of those not skilled in its use, and as making it more difficult to replace the intestines after sewing the wounds.

As to the technic, he said: (1) Unless the wound is well to one side, it is best to make a median incision, and it should be long enough to enable the operator to make a thorough examination of the abdominal contents. (2) The whole intestinal canal should, as a rule, be examined. (3) All peritoneal wounds should be sutured with silk Lembert sutures. Intestinal wounds should, other things being equal, be sewn in the long axis of the bowel. (4) If the liver is wounded, better results are obtained from packing than from suturing it. (5) If the kidney has been wounded, it is best to suture the peritoneal wound and treat the kidney extraperitoneally, if necessary. Of course, he did not refer to cases where the laceration and hemorrhage are so great that it is necessary to remove the kidney at once. (6) Drainage, except in late cases, is not necessary if all hemorrhage has been stopped. (7) Cases in which the intestines cannot be sutured without great risk of obstruction should be resected. (8) While enough time should be taken to do the work thoroughly, no time should be wasted. (9) Unless the bullet can be felt, search should not be made for it, as it causes unnecessary delay. (10) The superficial wound should be closed with silkworm-gut or silver wire, and the author believes that a single suture should include the skin, abdominal walls, and peritoneum.

Prognosis.—(1) The sooner the patient is operated upon the better the prognosis. (2) Those cases that have been reported in a series including all cases have shown a mortality of about sixty-two per cent. The prognosis is best in cases of wounds of the small intestine, and he believes that seventy-five per cent. of the cases will recover if seen early. By early, he means in the first two or three hours. (3) We all know that alcoholics stand all surgical work badly, and yet most of these patients have been drinking before they come under our care. The prognosis in non-alcoholics would be better than in alcoholics. (4) If the stomach and intestines are empty, the prognosis is usually improved.

After-treatment.—While not favoring drugging these patients, strychnin and other stimulants should be given hypodermically, if necessary. Especially should strychnia and alcohol in some form be given to alcoholics. Much depends on starting these patients well. If restless after the operation, or suffering, small doses of morphin should be given. If the stomach is quiet, and has not been injured, small amounts of water and Ducro's elixir can safely be given at the end of twenty-four hours, together with small quantities of milk, or some light broth. If the stomach has been injured, the feeding should be per rectum. The diet should be liquid for at least two weeks. If there is shock, with the clammy sweat that is sometimes seen, atropin, gr. $\frac{1}{60}$, should be given every three hours, as may be necessary. When shall we give a purgative? This is one of the most important questions that we shall be called upon to decide. If we give a purgative too soon the stitches may pull out, and if we wait, adhesions may form and give us trouble. The bowels of these patients will usually act spontaneously about the end of the fifth or beginning of the sixth day. If they do not, a mild purgative, assisted by an enema, should be given at the end of the sixth day, or on the morning of the seventh. As a rule, these patients should be kept in bed for at least two and a half weeks.

DR. JAMES MCFADDEN GASTON is very positive in his conviction of the propriety of laparotomy after gunshot wounds of the abdomen, and the sooner the better.

DR. N. P. DANDRIDGE of Cincinnati said that in gunshot wounds an exploration should be made in every case where there is reasonable supposition that the abdominal cavity has been entered. Gunshot wounds were much more serious than stab wounds. He had never succeeded in saving a case of gunshot wound of the intestine.

DR. A. M. CARTLEDGE had operated on five cases of gunshot wounds of the abdomen, three of them hopeless from the beginning, one dying within an hour and a half from a short operation, simply from the enormous amount of blood lost from a wound in the mesenteric vessel. He had never saved a case of gunshot wound with intestinal perforation.

DR. A. V. L. BROKAW of St. Louis considers every case of gunshot wound of the abdomen a law unto itself, and the surgeon has to meet the emergency as it occurs. He agrees with the essayist that a quick operation is absolutely necessary.

DR. W. E. B. DAVIS emphasized the importance of early operation, and called attention to the almost hopeless condition that is found if the surgeon operates after twenty-four or forty-eight hours.

DR. B. R. RHETT happened to have had three cases of gunshot wounds of the abdomen during the past year. In one case, a little boy, there were several intestinal perforations. He was operated on, but died within three hours thereafter. Case two died eleven hours after the closure of the perforations. Case three was that of a negro boy who had six perforations, and was operated on. The perforations were closed, and he made a good recovery.

DR. H. M. HUNTER of Union Springs, Ala., laid stress on the importance of early operative interference. He holds that very few patients will recover after twelve hours if not operated on, no matter how expert the surgeon may be. He had operated on a man, thirty-six hours after the receipt of the injury, who had two perforations of the colon, the ileum being just touched. The man died in three or four hours thereafter of general peritonitis.

DR. JOHN D. S. DAVIS does not believe it is possible to obtain seventy-five per cent. of recoveries from early

operations in injuries of the small intestine in private practice. The cases saved by Dr. Parker were operated on two hours after they were shot, hence early operation was the key-note to success. While he was not prepared to agree fully with Dr. Hunter that none of the cases could be saved after twelve hours, still the majority of them would die, if not operated on, within twelve hours. The most serious injuries to the belly from gunshot wounds were seldom followed by symptoms. There may be several intestinal perforations without the manifestation of any symptoms.

DR. F. W. MCREA had seen and known of several cases of penetrating wounds of the abdomen in Atlanta, all of which had terminated fatally, with one exception, and this patient was operated on by the late Dr. Armstrong. There were several perforations. A foot and a half of the small intestine was resected and the man recovered. The speaker would have some hesitancy in opening the abdomen where there was apt to be some medico-legal complication.

DR. HOWARD A. KELLY offered the following resolution which was unanimously adopted:

RESOLVED, That it is the sense of all the members of the Southern Surgical and Gynecological Association that in gunshot wounds, penetrating the abdominal cavity, the proper routine-procedure is to make an immediate exploratory incision.

DR. PARKER said, in closing, that the late Dr. Miles in his first series of cases reported thirteen cases, the percentage of recovery being nearly forty per cent. He had operated on probably twenty additional cases before his death, and the percentage of recoveries was very much better than in the first series. As to the medico-legal aspects of this subject, all surgeons should advocate the early opening of the abdomen, and if some fellow practitioner should get into trouble as a result of it, the profession should stand together and support him.

L. S. MCMURTRY, M.D., of Louisville read a paper entitled

THE EVOLUTION AND PERFECTION OF THE ASEPTIC SURGICAL TECHNIC.

The author cited cases where surgeons of world-wide reputation had infected their patients through some imperfection in the aseptic surgical technic, and said the subject deserves much more study and attention at the hands of operative surgeons than had heretofore been given to it. So far as instruments, dressings, etc., are concerned, surgeons had an absolute guarantee against sepsis in sterilization by heat; but when it came to the operative field, the hands of the operator and his assistants, they were reduced to mechanical and chemical methods of asepsis, which were certainly far less efficacious and reliable than sterilization by heat.

SECOND DAY—AFTERNOON SESSION.

E. S. LEWIS, M.D., of New Orleans, delivered

THE PRESIDENT'S ADDRESS.

Reference was made to the brilliant achievements of the masters of the art of surgery who had passed away, and of the galaxy of shining lights who had followed and who had created an era in the medical history of this century for all future time. How can we wonder that the "magnificent records obtained by experts have proved alluring temptations to the inexperienced and ambitious," and led to abuses which have left a blot on the fair page of abdominal surgery! As a body representative of the surgeons and gynecologists of the South, it should condemn the reckless and thoughtless plunging in this delicate and difficult work, without knowledge, fitness, or preparation. The statistics of the skilled who had learned to minimize risk and cope with difficulties. should not serve as an argument with the inexperienced to secure subjects. The responsibility of human life should not be ignored in the craving and struggle for notoriety or fame.

Speaking on the relative merits of the abdominal and vaginal operations, he commended the modified vaginal method of Doyen and others, as in touch with the conservative movement of the day, and in marked contrast with the ultraradical operation of Péan.

RICHARD DOUGLAS, M.D., of Nashville read a

MEMORIAL ADDRESS ON DR. PAUL F. EVE.

J. MCFADDEN GASTON, M.D., of Atlanta followed with a paper on

THE RELATIONS OF THE TUBERCULAR DIATHESIS TO ITS LOCAL MANIFESTATIONS.

He said that in considering the various forms in which tuberculosis shows itself in different structures, there must be an underlying element pervading the whole organism, which results from a general deterioration of the secretions. Whether there is a predisposition to the development of tuberculosis in certain parts or organs in advance of any constitutional disease or not, this change occurs in connection with the general impairment of the vital forces which characterizes the tubercular diathesis. While most recent authorities do not make a distinction between scrofula and tuberculosis, there is a fundamental difference in their general and local development. We have different characteristics of tuberculosis when it involves separate organs and structures of the body in a distinctly circumscribed form, or is defined as miliary tubercle in different structures, and yet the dyscrasia which marks the lymphatics under the designation of scrofula differs materially from any of the varieties of tuberculosis heretofore recognized. The presence of a condition recognized as a tubercular diathesis corresponds in some respects with the cachexia of carcinomatous tumors, and is held by many to be hereditary. It is fair to conclude that great caution should be observed in putting restraints upon the marriage of those suffering with pulmonary consumption, and the association of those laboring under this disease should be limited as far as practicable. Finally, the predisposition to tuberculosis cannot be relieved by a surgical operation upon the diseased structures, but must be corrected by remedial agencies acting through the absorbent and secretory organs.

SECOND DAY—EVENING SESSION.

A. V. L. BROKAW, M.D., of St. Louis read a paper entitled

THE RATIONAL TREATMENT OF THE DISEASED APPENDIX BY OPERATION.

He said the question had been vigorously discussed, is appendicitis a surgical disease at all times, or only surgical at times? He wished to be put on record as favoring the first proposition. He was aware that some ultraconservative practitioners claimed that the surgeon who advocated the removal of the appendix in every case when diseased, was a dangerous faddist and an extremist. He earnestly advocated early operation as soon as the diagnosis was made. Always operate when there is even a slight chance of saving a life, regardless of damage to statistics. Invariably operation should be insisted upon in the recurrent cases. With the knowledge of this dread disease evolved from the mortuary chambers, and the treacherous clinical course in a considerable percentage of cases, why should the rational treatment of all cases be other than by prompt surgery?

JAMES A. GOGGANS, M.D., of Alexander City, Ala., followed with a

REPORT OF CASES OF APPENDICITIS.

The main point at issue between the physician and the surgeon in the treatment of appendicitis depended much on a perfect diagnosis. This, too, accounted in a measure for their differences of opinion as to where the medical treatment should end, and when the surgical treatment should begin. According to his experience in the management of this affection, there is only one course to pursue, namely, to remove the appendix just as soon as the diagnosis has been made. Usually, before the operation, he gives a few small doses of calomel, followed by a saline purge, to evacuate the bowels. If opium were not given surgical interference might also save the patient.

DR. JOSEPH TABER JOHNSON looks upon appendicitis as a surgical disease, and believes it should be so treated. He deprecates the use of opium and considers it the patient's greatest enemy, in that it masks the symptoms and renders diagnosis exceedingly difficult.

DR. JAMES MCFADDEN GASTON spoke of the importance of making a distinction between cases of foreign bodies in the appendix and those of a catarrhal nature leading to a general inflammatory condition around the caput coli. Until we had inflammatory conditions which led to an exudate around the caput coli, it was difficult to determine definitely the exact condition which existed in supposed appendicitis. He was becoming more and more impressed with the fact that there were cases of appendicitis that were unattended with perforation, and these were curable without operative measures. An illustrative case was cited.

DR. F. W. MCRAE does not believe every case of appendicitis is a surgical one from the outset. A disease which shows so large a percentage of recoveries was not always an operative one. Treves and other English surgeons had shown that eighty per cent. of cases of appendicitis got well without operation. While demonstrator of anatomy, he examined every appendix which came upon the dissecting-table, and about 33⅓ per cent. showed evidences of previous inflammatory trouble around the appendix. The individuals, most of them convicts, had died of other diseases.

DR. HOWARD A. KELLY favored early operation. He alluded to the difficulty experienced in distinguishing appendicitis from tubal and ovarian disease of the right side, and related a case in point. In a woman with very high temperature and distended belly, he opened the abdomen, and evacuated a quart of pus. He found a gangrenous tube and ovary, as well as a gangrenous appendix. The patient recovered nicely from the immediate effects of the operation, but died on the thirtieth day thereafter from abscess of the liver.

DR. CHARLES P. NOBLE said the safest general rule was to operate as soon as a diagnosis of appendicitis was made.

DR. M. C. MCGANNON of Nashville recalled one case of appendicitis, a boy, in which the temperature rose to 105° F. The patient was delirious. Upon opening the abdomen, the appendix was found to be black but not perforated. It was easily removed, and the boy made a prompt recovery. He believes in many cases that if the physician waits and watches for distinct symptoms before operating, patients will die.

DR. A. J. COLEY had met with six cases of appendicitis, and made a strong argument in favor of early operative interference.

DR. A. M. CARTLEDGE said the more he operates the more he is inclined to believe we should operate on every operable case as soon as the diagnosis has been made. Mistakes were made by waiting and watching for symptoms to manifest themselves. Very few, if any, surgeons could tell when an appendix had been ruptured.

DR. GEORGE BEN JOHNSTON said, for the sake of statistics, operations for appendicitis should be divided into two classes: Those which are performed for recurrent attacks of the disease, and those which are employed for the relief of the severer varieties where perforation has occurred, or is likely to do so, or where pus is present. If the surgeon is to operate upon recurrent cases, it is better for him to do so between the attacks, in order that he may choose his time for operation. While there were cases of the disease that recovered without treatment, the best results were obtained by surgical interference.

DR. N. P. DANDRIDGE finds with increasing experience that he is more and more favorably disposed toward early operation; at the same time, cases present themselves in which he does not advise operative measures. He believes that some of the desperately bad cases were and could be saved by operation.

DR. R. B. RHETT said he had operated twenty times for this disease. He cited some interesting cases, illustrating the importance of early operation.

DR. W. D. HAGGARD, JR., called attention to the method of Gerster to prevent contamination of the peritoneal cavity in opening appendical abscesses that are

not adherent to the abdominal wall, or are not walled off. It consists in introducing thick layers of iodoform-gauze through the abdominal incision, and packing it between the walls of the abdomen and the abscess-sac itself, so that in the subsequent steps of enucleation there is no possibility of soiling the peritoneal cavity.

DR. D. FORD of Augusta, Ga., spoke in favor of early operation, believing that if cases were not operated on, sooner or later perforation would occur, followed by general peritonitis and death.

DR. W. E. B. DAVIS thought there were few cases of appendicitis that gave rise to general peritonitis, in which the surgeon could do any good. Frequently the surgeon was called too late. Even though the family physician recognizes the condition, it was not an easy matter to persuade the patient to be operated on within the first twenty-four hours, and unless these cases were treated surgically within twenty-four or thirty-six hours, very few of them could be saved. All cases of severe attacks of the disease, in which pain is intense, if seen the first day and consent is obtained, should be operated on. In all cases where there is a second attack operative measures should be resorted to.

DR. GEORGE A. BAXTER spoke of obliterating appendicitis, and asked the essayists to give their opinion of it in their closing remarks.

DR. BROKAW replied that obliterating appendicitis was nothing more nor less than the relapsing form of the disease, as a rule, or what had been termed "growling" appendicitis.

DR. GOGGANS said, in closing, that he could not better present his views on early operation than to say that if he had the disease, or peritonitis supervening upon it, he should demand operation. If he was so low that he could not stand a general anesthetic, he would take a local one, and would ask the surgeon to open his abdomen and remove the appendix.

H. M. MUNTER, M.D., of Union Springs, Ala., reported an interesting case of

COMPOUND COMMINUTED FRACTURE OF THE RADIUS AND ULNA, NEAR THE WRIST-JOINT.

He had been unable to find a similar case on record in the literature of fractures. There were three points with regard to this case: (1) That he was unaware of a similar fracture being reported. (2) He had never read nor heard of the method he had described to reduce the fracture of the forearm. (3) He had never seen nor read of such perfect results as were obtained in this case, the wrist having perfect motion; and there is absolutely no interference with supination and pronation.

DR. N. P. DANDRIDGE of Cincinnati reported a case of transperitoneal ligature of the external iliac artery for inguinal aneurism, in which he removed the aneurismal sac.

In the discussion, Dr. W. E. B. Davis also reported a case of ligation of the common iliac for aneurism of the external iliac, which was followed by an excellent result.

The following officers were elected:

President, Dr. George Ben Johnston of Richmond, Va.; secretary, Dr. W. E. B. Davis of Birmingham, Ala.; treasurer, Dr. A. M. Cartledge of Louisville, Ky.

Dr. E. S. Lewis of New Orleans was elected a member of the judicial council, to supply the place of Dr. Hunter McGuire, whose term had expired.

The Association then adjourned, to meet in St. Louis, Mo., the second Tuesday in November, 1897.

REVIEWS.

A MANUAL OF MATERIA MEDICA AND PHARMACOLOGY. Comprising all Organic and Inorganic drugs which are and have been official in the United States Pharmacopœia, together with important Allied Species and Useful Synthetics. For Students of Medicine, Druggists, Pharmacists, and Physicians. By DAVID M. R. CULBRETH, M.D., Professor of Botany, Materia Medica, and Pharmacognosy in the Maryland College of Pharmacy, Baltimore. In one octavo volume of 812 pages, with 445 illustrations. Lea Brothers & Co., Publishers, Philadelphia and New York, 1896.

THIS book is a distinct addition to those already existing in that it sets a high idea of knowledge to students of pharmacy. As our country grows older we are demanding more and more from the rank and file of this profession. We demand not only a working knowledge of drugs, but that clear, complete basis of scientific attainment upon which alone intelligent original work may be founded. This demand has led the author, for many years engaged in teaching, to prepare the book we are discussing.

The manual will be pleasing to the medical profession on account of the absence of any attempt to include more medical knowledge than is necessary to understand toxicology; for, though medicine must include a knowledge of pharmacy, the pharmacist is not concerned with the science of medicine, except in that small portion of it comprised in a limited knowledge of toxicology, and a limited knowledge of therapeutics. The author of this book evidently realizes what layman and even pharmacists sometimes forget, namely, that therapeutics, though the culmination of medical training, comprises in reality not more than one-tenth of the science of medicine, and that a knowledge of pharmacy should not afford a basis for the practice of medicine.

In this book the reader will find a complete though concise description of materia medica, both organic and inorganic, arranged in a convenient form for study or reference. To the pharmacist, the book will immediately commend itself, but we would urge its study upon the physician also. In the separation of medicine from pharmacy, as was found necessary in early days, physicians lost much and are constantly losing more. A familiarity with a good book on materia medica might do much to retrieve that knowledge of the individual properties of drugs in which the physician of former times was so much superior to the younger man of to-day. These older physicians are sometimes criticized for their habit of prescribing elaborate mixtures, and giving many drugs at one time, but these mixtures were devised for the individual case, and each

drug was given with a specific purpose. With this in mind these ancient prescriptions should not be thoughtlessly criticized without realizing the more grave pharmaceutical vice of to-day, found in the habit of using manufactured pills and mixtures. This has brought about a deficiency in the knowledge of the properties of individual drugs on the part of physicians that is hardly credible. A study of Gilbreth's book in the place of the therapeutic catalogs of manufacturing druggists would do much to remedy this evil. A return to the general use of carefully written and skilfully compounded prescriptions would be a happy reaction from the abuse of ready-made tablets, pills, and proprietary mixtures. Such a reaction can only follow from a better knowledge of drugs by physicians, and a confidence on their part that the pharmacists are maintaining a high ideal of scientific work.

We can conscientiously recommend this book, not only for its contents, but also for the convenience of its arrangement and the elegance of its typography and general make-up.

THE STUDENT'S MEDICAL DICTIONARY. Including all the words and phrases generally used in medicine, with their proper pronunciation and definitions, based on recent medical literature. By GEORGE M. GOULD, A.M., M.D. Tenth edition, rewritten and enlarged. Philadelphia: P. Blakiston, Son & Co.

IT may be accepted as axiomatic that lexicography more than any other department of bibliopoesy calls for unceasing vigilance to prevent blunders and insure a harmonious whole.

Dr. Gould has on the whole emerged with credit from this ordeal. The definitions are generally marked by terseness, accuracy, and an absence of what the most eminent philologist in the United States has termed the "talkee-talkee" element. It is particularly pleasing to find that words which have recently come into use are so well represented. The vocabulary of biological medicine, however, might well have been fuller, and of words in general use "chromicized," "hematokolpos," "blastomycetic" and "paperaceous" have been searched for in vain. "Syphilography" is given, but "syphilology" and "syphilologist" are not.

The cross-reference department shows a sad lack of supervision. To be specific: For the definition of Eberth's bacillus reference is made to the table of bacteria, and for crab-louse to *Pediculus*, but neither is to be found under the words cited. Seidlitz powder has an impertinent reference to potassium, since the definition of the phrase is to be found under pulvis. Thread-worm (of which the proper definition is any nematode worm) is defined, "see *Oxyuris*," which is defined "a genus of nematode worms, the pinworms. "This is referred for definition to *Oxyuris*. Under worm, thread-worm appears again, this time referred to *Oxyuris* and *Trichocephalus*, the definition under the latter word is "the thread-worms." In the definition of worm, the "class" *Vermes* is spoken of, but there is no such class in modern zoology.

Psorosperm in view of its association with the malarial fevers receives a definition, which is most inadequate, presenting no diagnosticating features from other protozoans. Abrasion is very much more commonly used in medicine for the surface abraded, and should have been so defined rather than "the rubbing-off of the cutaneous or mucous surface by an injury." Anthracemia and anthrax, though synonyms, both receive definitions. A cross-reference from the former to the latter would have sufficed. Eosinophile should have had a nounal definition.

The species of *Saccharomyces* appear under a "Table of Bacteria," though that genus is in no legitimate sense bacterial, being very different morphologically. Tables of statistical matter have no proper place in a dictionary whose province is restricted to the treatment of words as such and word-forms, but they are generally inserted as a concession to publishers.

There is a well-marked freedom from typographical errors, though *Saracosporidia* occurs on page 594 and *Absinthum* on page 663. Specific names appear generally in italics, but not infrequently in roman (see *Bacillus anthracis* on page 63, and bacillus anthracis on page 64), and the anachronism of capitalizing vernacular names of plants is also observable.

The appearance of the page leaves nothing to be desired and is worthy of De Vinne himself.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE 16 DAYS ENDED OCTOBER 31, 1896.

PURVIANCE, GEORGE, surgeon, placed on waiting orders from November 5, 1896.—October 27, 1896.

SAWTELLE, H. W., surgeon, detailed to represent Service at Pan-American Congress, to be held in city of Mexico, October 28, 1896.

WHEELER, W. A., surgeon, granted leave of absence for three days, October 16, 1896.

PECKHAM, C. T., passed assistant surgeon, directed to proceed from Port Townsend, Wash., to Detroit, Mich., for duty, October 27, 1896.

GLENNAN, A. H., passed assistant surgeon, granted leave of absence for nine days, from December 23, 1896.

PETTUS, W. J., passed assistant surgeon, to assume temporary command of Service at Norfolk, Va., in addition to his other duties, October 24, 1896.

MAGRUDER, G. M., passed assistant surgeon, detailed as Inspector of Immigrants at Galveston, Tex., October 24, 1896.

WERTENBAKER, C. P., passed assistant surgeon, to proceed from Delaware Breakwater Quarantine to Philadelphia, Pa., for temporary duty, October 16, 1896.

YOUNG, C. B., passed assistant surgeon, leave of absence extended five days, October 16, 1896.

NYDEGGER, J. A., passed assistant surgeon, to proceed from South Atlantic to Brunswick, Ga., Quarantine, for temporary duty for thirty days, October 26, 1896.

NORMAN, SEATON, assistant surgeon, granted leave of absence for five days, October 22, 1896.

PROCHAZKA, EMIL, assistant surgeon, to proceed from Cairo, Ill., to Delaware Breakwater Quarantine, for temporary duty, October 16, 1896.

CUMMING, H. S., assistant surgeon, relieved from duty at Evansville, Ind., and directed to rejoin station on expiration of present leave at New York, N. Y., October 22, 1896.

RESIGNATION.

HAMILTON, JOHN B., surgeon, resignation accepted, to take effect November 13. 1896.—October 16, 1896.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXIX. NEW YORK, SATURDAY, DECEMBER 5, 1896. No. 23.

ORIGINAL ARTICLES.

PNEUMONIA IN CHILDREN.[1]

BY J. P. CROZER GRIFFITH, M.D.,
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE UNIVERSITY OF PENNSYLVANIA.

THE subject of pneumonia in children is too large to be discussed in its entirety on this occasion. I must confine myself to a review merely, giving particular attention to the characteristics seen in subjects under five years of age, and especially of those of two years and less. As the child grows older the unusual characteristics of the affection disappear more and more, and the symptoms finally become identical with those seen in adults.

The element of age is a very important factor in producing one or the other of the two forms of pneumonia. It would seem now generally admitted that croupous pneumonia may attack subjects of any age, although it is distinctly less frequent in children under one year old and more frequent after five years. Bronchopneumonia, on the other hand, is by far the commoner and more fatal form in children of less than five years, and especially in infants. At the same time no one is justified in pronouncing a pneumonia to be of the one form or of the other upon the age-factor alone.

The cough of pneumonia is peculiar and characteristic. It is short, sharp, and painful, and consequently repressed as much as possible. The fact that it hurts, often makes an expression of pain pass over the face of a pneumonic infant, and causes the utterance of a short cry. Sometimes in children cough is nearly or quite absent.

The difficulty in breathing gives the child no time to cry; and this suppression is a very characteristic feature. One form of cry is the well-known "expiratory moan," which is often present in severe cases. With many of the expirations a short moaning or sighing sound is made. One of the most characteristic symptoms of pneumonia is the very rapid respiration, frequently 70 or 80, or even more in the minute. The rapid breathing is clearly dyspneic also, as evidenced by the moving alæ, the tugging sterno-cleido-mastoids, the sinking in of the episternal notch and the drawing in of the lower ribs and the interspaces by the action of the diaphragm. It is the dyspnea, indicated by these symptoms, that makes the little patient unwilling to lie quietly in bed. Often the most comfortable position in the case of an infant seems to be in the nurse's arms, with the head over her shoulder.

It is a noteworthy observation that, whereas in normal breathing the accent, so to speak, is upon inspiration, in pneumonia expiration is made with the greater force.

There are some interesting peculiarities about the *physical signs* of pneumonia in children to which further reference may well be made. In the first place, there is a striking lack of correspondence between the symptoms, and the signs discovered by physical examination of the chest. Then there is the tendency for all physical signs often to develop very slowly. I have frequently in croupous pneumonia failed to find satisfactory physical signs until the disease was well under way, or, indeed, until after the crisis had occurred. Among the conditions which render percussion difficult and unsatisfactory in childhood is the peculiar resiliency of the chest at this age. Unless the blow be light and percussion carefully performed, it is very easy to overlook a limited area of dulness which could easily have been found. It is as much or more the sensation of resistance to the finger which we must seek, as it is any alteration of the sound. Too hard a blow makes the whole chest reverberate and prevents the possibility of local differentiation. I find a series of rapid light blows the best method as a rule. But in spite of the greatest care it sometimes happens that a child will pass through an attack of pneumonia without at any time revealing a dulness on percussion. Indeed, it often happens that the affected side is tympanitic rather than dull. I do not refer to the high-pitched wooden tympany of Skoda, which may often be observed in subjects of any age, but to a full, deep note which may be audible over a whole side, or, perhaps, only in front, while the back is dull. This tympany may occur in adults as well, but is much oftener heard in children. Quite often it is present even when there is distinct alteration of the auscultatory sounds over the same area. Often,

[1] An address delivered before the Lycoming County Medical Society.

indeed, we may make a diagnosis as easily from the tympanitic note as we could from an impairment. The tympany may last several days and then may or may not be replaced by dulness; or a part of the lung may grow dull and another part may remain tympanitic in spite of other signs of consolidation. This condition of tympany may continue nearly, or quite, until the crisis has taken place. The brief details of the following case—not an unusual one—illustrate this fact:

Susie A., aged six years, was taken suddenly ill with fever and headache. Examination showed numerous scattered râles in the lungs with increased vocal resonance on the right side in front and a decided tympanitic note there. The provisional diagnosis of pneumonia was made. Upon the following day below the right clavicle there were greatly increased vocal resonance and a percussion-note which was more tympanitic and lower pitched than upon the left side. On the fourth day, harsh expiration was added to the other physical signs in front, while behind, down to the angle of the scapula, there was a slight impairment of percussion-resonance. On the sixth day the tympanitic note in front was unchanged, but respiration had become decidedly bronchial. Only by the eighth day of the disease had dulness appeared in front with a still further increase of the other physical signs of consolidation.

Repeatedly in bronchopneumonia the most careful examination will reveal merely a very small area in which there is some impairment of resonance. This condition is the natural result of the diffuse nature of the lesion, only small lobular areas here and there being involved in many cases.

In typical cases of croupous pneumonia the auscultatory signs are naturally the same as in adults. In other cases, however, which are nevertheless just as distinctly pneumonic, either of the croupous or the catarrhal form, a weakening of the respiratory murmur may be all that can be detected; or perhaps there is a slight roughening of it, or a slight prolongation of expiration. In many other instances there is no alteration whatever to be discovered. This occurs in cases in which the lesion is very small, or perhaps centrally located.

It is important to remember that bronchopneumonia is quite usually, and croupous pneumonia not infrequently, preceded by a bronchitis. Consequently mucous râles may perhaps be found present during the whole course of the attack. In many instances we may base a diagnosis upon these râles. In bronchitis, for example, the râles are wide-spread, or, if heard in one situation one day, are very likely to be audible only in another place upon a subsequent examination. If, however, we find râles which persistently remain audible in only one place, we have reason to presume that in this spot there is an area of pneumonic lung. The true crepitant râle is sometimes heard, but oftener not found. A peculiar ringing quality, what may be called an increased vocal resonance of the râle, is often present and is very characteristic of pneumonia. It has not infrequently happened that I have been able to locate a bronchopneumonic area by noticing that whereas the râles in other parts of the lungs were all of one kind, those audible over a small area had this peculiar character described. In the absence of cry this may be our only way of testing vocal resonance; and in my experience vocal resonance is one of the most reliable tests for pneumonic lung in children. If the child does cry it is likely that we can hear some increase of vocal resonance in the area to which the râles have drawn our attention.

There are several minor subdivisions of pneumonia described, some of which are rather more characteristic of children than of adults. Prominent among these is that known as *abortive pneumonia*. In this class are contained the cases so commonly described as "congestion of the lungs," a term which is much better omitted from our medical literature, so far, at least, as it relates to a condition bearing any relationship to pneumonia.

Abortive pneumonia is seen especially in children. All the ordinary earlier symptoms of croupous pneumonia are present, but the physical signs are usually almost negative, and the whole process stops suddenly in a few days. In a smaller number of cases distinct physical signs develop, but rapidly resolve, just, perhaps, as we expect to encounter a severe case of the disease. Although abortive pneumonia must be familiar to all, I venture to give the following history:

A. A., the one-year-old child of a physician of Philadelphia appeared to have taken cold on the night of March 14th, and on the morning of the 16th had some fever and nervousness, and a cough, which appeared to be painful. A few diffuse râles were audible in the chest. By the afternoon of the same day he looked very ill, had a temperature of 103° and respiration of 80, with some cyanosis. Numerous râles were heard in both lungs, but no evidence of consolidation was found. The child presented all the appearances of a case of beginning croupous pneumonia, but by the next day, the 17th, after not more than thirty-six hours' sickness, he was very greatly better, with a total change in his general condition. His state continued to be excellent, without fever, but with rather numerous, although

diminishing, coarse râles in the chest. Not until about a week after the first development of symptoms was a decided increase of vocal resonance discoverable over the upper part of the right lung behind.

This case is not only a beautiful instance of a form of abortive pneumonia, but it exemplifies, too, the late development of physical signs in some cases.

Creeping or wandering pneumonia is a well-recognized form in adults as well as in children. It is, perhaps, oftenest seen after influenza, but may occur independently of this. One part of the lung is affected, then another while the first clears up, the symptoms meanwhile continuing in full force, so that the course of the affection may be unusually prolonged. Of course, the ordinary attack of bronchopneumonia is of a creeping nature, the process gradually extending from one part of the lung to another, usually, however, with no tendency to resolution until the attack begins to approach a favorable termination.

Cases exhibiting a pseudo-crisis cannot be called true instances of wandering pneumonia, nor, strictly speaking, of relapse. In this condition the temperature falls, and convalescence seems established, when there is another rise, perhaps with an involvement of some other part of the lungs. It may be that the temperature is not quite normal, yet the condition of the child is such that immediate recovery is expected. In a case which I recently saw in consultation, a little boy of twenty-three months had suffered from an attack of croupous pneumonia in the left lung, beginning October 16th. On October 19th the temperature was 105°, but on the 20th it had fallen to 100°, all the symptoms were greatly improved, and the physician in attendance had very properly pronounced the child about to convalesce. Upon the following day, however, there was a sudden return of all the symptoms in an aggravated form, together with physical signs of consolidation in the other lung. This second attack lasted several days. When I last heard of the child, about three weeks after the onset of the disease, he was running about in perfect health, as it seemed, but with the physical signs of consolidation unchanged—another instance of the delayed resolution, to which reference will be made later.

Pneumonia gastrica is a well-marked form in children. The attack starts with vomiting, coated tongue, pain in the abdomen, and perhaps diarrhea; and only after a day or longer can the diagnosis of pneumonia be made. The following case shows how pneumonia may develop in this way, and the family suspect no more than a severe attack of indigestion:

Harry A., aged about eight years, was taken sick October 18, 1886, with headache, high fever, and vomiting. The vomiting continued unabated on the 19th, and on the 20th, the third day of the attack, the child was worse than at any preceding time. There was now great loss of appetite, with fever, thirst, and slight delirium, and vomiting of everything taken. There was a loose bronchial cough merely, such as he had had for several weeks. When I first saw him, on the fourth day of the disease, he was still vomiting as before, his temperature was 101.2°, and there were also found distinct physical signs of pneumonia in the right lung. By the 23d, the sixth day of the disease, the child was convalescent and the physical signs had nearly disappeared.

Finally we may mention cerebral pneumonia, in which the disease appears to be a meningitis rather than an affection of the lungs; or in which the early symptoms for some days are cerebral rather than pulmonary. The following case illustrates the nervous symptoms accompanying this form:

Ambrose G., aged five and one-half years, was taken sick on February 13th with headache, vomiting, and moderate diarrhea. February 14th, condition was unchanged, except that the diarrhea had almost ceased. February 15th. Seemed bewildered in the morning; quite delirious during the greater part of the remainder of the day. Temperature 103° at eight P.M. February 16th. Diarrhea and vomiting ceased. February 17th. Still delirious at times, especially at night. Temperature for the last two days 102 to 104°. February 18th. General condition rather better. No complaint. No tenderness anywhere. Had been having a slight cough, but nothing of note. February 19th. Seems very dull most of the time. Temperature 103°. Very little cough. Dr. Wm. Osler, who saw the child with me on this date, considered the diagnosis obscure, but leaned toward typhoid fever or tuberculosis. February 21st, the ninth day of the disease, there were physical signs of pneumonia present for the first time, *viz.*, bronchial expiration and broncophony below the right clavicle. The temperature was falling, and was now 101° and a fraction. February 23d, the eleventh day of the attack, the temperature was 99°, and the child in good spirits and rapidly convalescing. The auscultatory signs of pneumonia were, however, even more marked than before, in spite of the low-pitched tympany over the affected area. There was, and had been, very little cough.

Different as croupous pneumonia and bronchopneumonia usually are in their symptoms, so, too, are they unlike in their pathological anatomy.

Like, too, as the symptoms are in some cases, so even at the autopsy we may be at times not able easily to complete a diagnosis which was uncertain during life. In some instances we may find *post mortem* a combination of a fibrinous and a catarrhal inflammation. There may be either an inflammation of one sort in one part of the lung and of the other sort in another, or it may even be that the fibrinous and the catarrhal processes are intimately associated. Of course, in ordinary cases the characteristic of croupous pneumonia is the exudation of fibrin within the vesicles. The lung, a lobe, or perhaps only a small portion of pulmonary tissue presents the firm, granular, liver-red appearance so well known. In bronchopneumonia the characteristic is the peribronchial and perialveolar inflammation. The whole lung does not compress as well as it should, and some hard nodules can be felt here and there in it. Section of one of these pneumonic nodules shows this portion to be light-colored and more projecting than the surrounding dark-red collapsed areas and the healthy lung-tissue. Close inspection of the affected region shows small bronchioles, whose lumen is filled with mucus and whose walls are thickened and whitish. In many cases of bronchopneumonia nearly a whole lung may be apparently uniformly consolidated; but even then bands of healthy tissue may be found, and careful examination shows the characteristic appearance of the bronchioles.

In acute tubercular bronchopneumonia the process rapidly goes on to the formation of cheesy nodules, and to a breaking down of lung-structure if the child lives long enough. We must remember that it is never by the fact that the disease is lobular, that the diagnosis of bronchopneumonia can safely be made since fibrinous pneumonia does not need to attack a whole lobe of a lung, and bronchopneumonia, as just stated, may do this. It is on the minuter characteristics described that the diagnosis must rest.

In croupous pneumonia, while any part of the lungs may be affected, the apices seem to be involved oftener than they are in adults. Statistics indicate that the disease is commonest at the right apex, and next so at the left base. This liability of the process to occupy the apex in children is frequently forgotten, and, as a result, the lesion is often overlooked when making a physical examination of the chest. It has long been claimed that apical pneumonia is especially liable to be attended by cerebral symptoms. This is a point which is now much disputed. In my own experience I have not been able to detect any especial tendency to cerebral disturbance in cases of apical localization. In croupous pneumonia the disease is unilateral in the greater number of cases. In bronchopneumonia on the other hand, the disease is usually bilateral if the case is at all a severe, prolonged one. The apex, however, is not commonly involved in this form, except in tubercular cases.

We may now properly turn to the question of the diagnosis of pneumonia; or, rather, to some of the difficulties which attend it, for the points which are entirely clear may well be omitted in this sketch. Croupous pneumonia is often peculiarly like scarlet fever in its onset. The sudden rise of temperature, with rapid pulse, and with the convulsion or vomiting, which so often ushers in both diseases, may leave us in doubt at first.

Croupous pneumonia can hardly be confounded with bronchitis, unless in exceptional cases, but bronchopneumonia must be carefully distinguished from it. This is often a difficult matter to determine, particularly when the bronchitis, which usually precedes, has had added to it the pneumonic condition. Bronchitis is rarely accompanied by much fever or by dyspnea of any moment. When, therefore, in the course of a bronchitis, there is a rise of temperature, accelerated respiration, and a change of the loose or harassing cough to one which is short, painful, and suppressed, we have reason to believe that pneumonia has developed, in spite of the absence of physical signs. When the diagnosis is doubtful, we may take it as a pretty safe rule that we have to do with pneumonia, rather than bronchitis. Here I may say a word about the so-called *capillary bronchitis*. I have never seen a case of pure capillary bronchitis, and the best authorities are disposed to deny the existence of such an affection as an independent disease. While it is conceivable that the smallest bronchial tubes might be involved independently of the alveoli, yet, as a matter of fact, it is probable that this never occurs. Certainly, we are not justified in calling a case one of capillary bronchitis merely because we fail to find signs of consolidation. Of course, the beginning of every bronchopneumonia is a capillary bronchitis, but the process does not stop here, and involvement of the alveoli rapidly follows.

The diagnosis between bronchopneumonia and croupous pneumonia is often easy, often difficult, and often impossible. This last must necessarily be the case sometimes, owing to the existence of mixed forms. In croupous pneumonia the onset is sudden, there are the usual

signs of pneumonia as seen in the adult, the course is short, and the termination is generally by crisis. In bronchopneumonia, on the other hand, the onset is gradual, the dyspnea often greater, the temperature rises more slowly, and its course not so high and more irregular, and the termination, if favorable, is by lysis. The physical signs, too, are more indefinite, dulness being less marked and the alterations of the respiratory murmur more difficult to detect. Yet this statement of the differences is open to numerous exceptions. In bronchopneumonia the onset may be sudden, with convulsions and high temperature, and we may have an area of consolidation develop in which the physical signs are as marked as in cases of croupous pneumonia. On the other hand, in the latter disease the lesion is sometimes very limited, or even undiscoverable. The following case, in its onset and the rapidity of its development, had the most characteristic appearances of the croupous form, although its course, and still more the autopsy, showed that it was not such:

Katie H., aged three years, had had no appetite and had not seemed perfectly well for several weeks, and had had an insignificant cough; but had been playing about. On the evening of February 1st, she developed fever and accelerated respiration with a catch in it. February 2d, temperature in the morning, 104°; respiration of the same character as on the preceding day; alæ moving; frequent, short, hacking cough; numerous fine crepitant superficial râles at the base of the right lung, in front and behind. February 3d, the third day of the disease, respiration rapid; cheeks flushed, short, suppressed cough; bronchial expiration over the middle of the right lung behind. February 4th, marked bronchial inspiration and expiration over the middle of the right lung behind. February 5th, child a little cyanotic; marked dulness over the upper two lobes of the right lung. Delirium set in; fever continued, but was of an irregular type, and respiration was much labored. On February 11th, the eleventh day of the disease, the lower lobe of the right lung became involved. On the 13th there was a fall of temperature to 99°, with cold sensations, and it appeared as though crisis had taken place, but on February 14th the temperature rose again, and there were indications of general involvement of the other lung. On February 16th there were very many mucous râles everywhere. These had been present in increasing numbers from early in the disease. The condition of the child grew worse from this time on, yet without increasing consolidation, and even with apparent improvement in some of the physical signs. Death took place on February 25th, the twenty-fifth day of the disease. The diagnosis was croupous pneumonia, yet with a very anomalous course. The autopsy, however, showed a wide-spread acute tuberculous bronchopneumonia in both lungs.

Such a case as this is sufficient to upset all one's preconceived ideas about the diagnosis of the two forms of pneumonia. Fortunately, such a striking similarity in the early symptoms is not often observed, for I know of no way whatever to arrive at a certain diagnosis.

In children, the difficulty of diagnosing pneumonia from pleurisy is enhanced by the fact that the breathing in cases of effusion is often very tubular, and that fremitus may even be present. The hypodermic needle will usually settle the question, and may be relied on as the most certain method of diagnosis. But even this sometimes leaves us in doubt, for a "dry tap" is, for various reasons, sometimes obtained, even when fluid is present. It is seldom, however, that repeated tappings will fail to reveal fluid if there is any. The following case was one of great interest and perplexity to me at the time, and one which so well illustrates the difficulty of diagnosis, that I may give it in brief here:

Catherine M., aged eleven years, had had for some time fairly well-compensated valvular disease of the heart. When first seen, October 19th, she had been suffering for three days from what her physician had pronounced to be pneumonia. Examination on this date showed the usual symptoms of pneumonia, with the physical signs, *viz.*, dulness of the left axilla, left base behind, and right apex behind, with bronchial breathing over the dull areas. On October 23d, four days later, the dulness was extreme on the left side, particularly below, and there seemed to be some shifting of it, with change of position, making the presence of fluid possible. Yet tactile fremitus was but little diminished, and the voice was distinctly transmitted. The diagnosis being in doubt, a hypodermic needle was used, but gave a dry tap. On the next day, October 26th, vocal fremitus was absent over the left chest; the dulness increased as the base was approached; the breath-sounds, although audible, were faint —all speaking for effusion. On the other hand, the heart was not displaced, the interspaces moved in with inspiration, there was no alteration of the line of dulness with change of position, and very distinct mucous râles could be heard over the dull area—all this speaking for consolidation, with deficient action of the lung. On November 5th the left side measured three-eighths of an inch more than the right; the respiratory murmur was distant and vocal resonance feeble—speaking for effusion. On the other hand, the bulging præcordium from chronic heart-disease could easily account for the enlargement of the left side, and the heart was still beating in the normal position. On November 11th the

movement of the chest was chiefly on the right side, the dulness was still very marked in the left axilla and behind; vocal fremitus was absent, the breath-sounds feeble, spoken words reached the ear indistinctly. Moreover, this was now the twenty-fifth day of the attack. All this seemed to indicate, beyond doubt, that there was a pleural effusion. However, the heart was in the normal position, and occasional râles could be heard at the base and in the axilla. Besides this, repeated tappings during the days past had failed to find fluid. About this time, too, I was convinced by the intensity of the transmitted sound of the cough that I had to do not with effusion, but with a delayed resolution in a consolidated lung which did not expand, and the tubes of which were probably blocked with mucus, so that the air did not enter it to any extent. The further course of the case confirmed the diagnosis, for as the lung began to resolve and to have air enter it, the signs of consolidation again showed themselves as at first, and there were none of the series of alterations of physical signs characteristic of a disappearing effusion.

Cases of this nature repeatedly occur, in which the diagnosis upon one day seems to lean toward consolidation, and upon the next toward effusion. The possibility of the combination of the two diseases renders the diagnosis still more difficult.

Delayed resolution in pneumonia is a matter to which far too little attention is given in most textbooks, since it is a condition which greatly obscures the diagnosis. One is unable to satisfy one's self by consulting medical literature how long a pneumonic consolidation may persist and yet indicate no phthisical changes. In adults I have repeatedly seen resolution delayed for weeks, and in children this seems to be even more frequent. In many cases of delayed resolution the fever subsides and yet the consolidation continues; but in other cases the fever persists. In the case just related the consolidation was present for at least nine weeks. In the following case the delay of resolution was even greater:

S. A., girl of six years, was attacked toward the end of September by croupous pneumonia, which involved first the right lung, and then the left, the right side meanwhile clearing up. Resolution was thus delayed, and the temperature fell by lysis, reaching normal by the nineteenth day of the disease. At this time purpura developed as a sequel. The child recovered from this attack and was out of bed in about a month after the onset of the pneumonia. The left lung still showed loud bronchial breathing, bronchophony, and dulness, on percussion. The child was not seen again until the following March, a period of five months. At this time she was running about apparently well, except for a loose, troublesome cough. The lung was still consolidated throughout, with bronchophony, coarse mucous râles, and other signs which made me believe that there undoubtedly was phthisical softening going on. Later, after a period of several months more, I saw the girl again and found her entirely well. The consolidation must then have lasted decidedly over five months.

The delayed resolution spoken of appertains to croupous pneumonia. In bronchopneumonia, too, resolution is sometimes very unusually delayed. The following case indicates that hope may never be abandoned in this disease until death is actually present:

Mamie C., aged about two years, was admitted to the Children's Hospital in Philadelphia in the early spring, suffering with bronchopneumonia. There was a well-marked patch of consolidation in the upper part of the right lung behind. There was daily fever of a somewhat hectic type. The child constantly grew paler, and more wasted, and had every appearance of being a sufferer from phthisis. In the course of the summer she was several times sent to the County Branch of the Hospital in the hope that the fresher air would do her good; and several times was returned to the main hospital apparently in a dying condition. By the autumn she commenced to improve, and did so rapidly, losing at last all consolidation, and regaining entire health.

I may say of this case that I never felt more sure of a diagnosis of phthisis, and had never less hope of any improvement whatever; also that the attendants were on several occasions daily expecting the child to die. Her final recovery, therefore, was a correspondingly great surprise.

I have still to refer to the curious cases of pneumonia in children in which the cough is nearly or entirely absent. The case of Ambrose G., already referred to, was an instance of a very slight development of cough, and the following case illustrates its absence in a still more striking manner:

Mary Agnes McC., aged eight years, was admitted to St. Agnes Hospital, October 27th, suffering with chorea. She was put to bed and given Fowler's solution. Improvement continued until November 15th, when she became suddenly ill. Her pulse rose to 170, and her respiration equaled 80 and 90, and was quite shallow. She complained of great abdominal pain and tenderness. A purgative, followed by an enema, and by turpentine stupes, gave no relief. As her aspect was that of a very ill child the resident physician called upon me to tell me of the case, saying that he feared arsenical poisoning. After careful questioning I assured him that there were no toxic symptoms, but said that I suspected peritonitis. Upon the following day I saw the child in the presence of several physicians from the Philadelphia Poly-

clinic, and none of us had any doubt that we had to do with a peritonitis. The feet were drawn up in bed, the abdomen distended and very tender, and the expression anxious. There was some fever, and the child complained of abdominal pain. The respiration was shallow and rapid, as one sees it in a peritoneal inflammation. Although there had been no cough whatever I examined the chest as a matter of routine, and was surprised to find well-developed signs of pneumonia in the upper part of the right lung. Upon the next day, the 17th of November, the abdomen, although still tender, was much better, and by evening all pain had disappeared. It was evident by this time that the diagnosis of peritonitis was untenable, and that the pain was evidently a referred pain. The pneumonic condition rapidly extended, the attack was an unusually severe one, cyanosis set in early, and the child died on the 18th or 19th. Cough was so little of a feature that there is some disagreement among the attendants whether there was any at all.

This tendency of children to refer pain to some other part of the body than that where it is actually produced is well known. The case just related exhibits pain referred to the abdomen; for there was no reason to think, as the course of the disease progressed, that there was also a peritonitis. As a counter-case to this, emphasizing the difficulties in diagnosis, I may mention an instance which occurred in the Children's Hospital during the service of one of my colleagues, in which peritonitis was supposed to be pneumonia.

The likeness of pneumonia to cerebral affections, and particularly to meningitis, has already been mentioned in speaking of cerebral pneumonia. Sometimes the diagnosis is impossible, particularly in the light of the fact that the two diseases are often combined. Many a child with pneumonia will show well-marked symptoms of meningitis, and yet have no inflammation of the meninges.

With regard to prognosis, the very great majority of cases of croupous pneumonia in previously healthy children will recover. The prognosis of bronchopneumonia is very much less favorable, and the bronchopneumonia consecutive to measles, whooping-cough, or diphtheria is one of our most fatal affections.

In considering treatment we must first attend to prophylaxis. The great danger of bronchitis in infants is its tendency to run into bronchopneumonia, and even croupous pneumonia not infrequently follows a few days of bronchitis. Consequently, every child must be carefully guarded against taking cold, and be most carefully treated if bronchitis is already present Suitable hygiene of the house and of the clothing, and of the life in general, will aid in the first; confinement to bed and proper medication, external and internal, fulfils the second indication.

Regarding the treatment of an attack of pneumonia, I may first speak of the use of applications to the chest. The cotton jacket has not, in my opinion, any of the great value which is attributed to it by so many practitioners. I have treated children with it and without it, and I have never been able to see that those without it were any worse off. If the jacket is applied with the idea that we thus prevent taking cold and increasing the pneumonia, we are working upon an entirely incorrect principle; for, since croupous pneumonia is an infectious disease, the influence of "taking cold" is probably slight when the disease is well under way. We well know, too, that it is by no means the part exposed which suffers, even in a general cold. For instance, wetting the feet is a common source of cold in the head. For the same reason, then, that we wrap the chest up in cotton in pneumonia, we should envelop the whole body in cotton in order to avoid chilling of any region, and thus increasing the pulmonary disease. Indeed, the use of a cotton jacket renders the skin more susceptible when the physician makes his examinations of the chest; and if it is capable of doing good, it is equally capable of doing harm. Of course, these statements do not mean that we should be reckless in exposing the child to chilling. All draughts are to be carefully avoided, and the child must constantly be properly covered with bed-clothes.

Here I may say, however, that we, as physicians, should hold in check the strange desire so many mothers have to burden a feverish child with a vast quantity of bed-covers. Infants cannot, of course, complain, and even older children, when apathetic, as they become with the disease, will not make complaint of being too hot.

What I have said with regard to the cotton jacket applies in some respects to the use of the jacket-poultice. I would strongly protest against its routine employment. There is not any evidence that the poultice is in any way curative, and it is certainly often heavy and uncomfortable, and renders respiration more difficult. This statement, like the last, is open to exceptions, and I by no means intend to condemn the poultice absolutely—only its routine employment. It should be used for exceptional cases, and with a definite purpose. I have seen the application and frequent renewal of a light, hot jacket-poultice give the greatest relief in the intense dyspnea which

is particularly apt to accompany bronchopneumonia. I do not know how it acts in these cases, unless by relieving the bronchitis, but the good it does in ameliorating the symptoms is sometimes very prompt and decided. Care must be taken that the poultice is properly applied, as otherwise it soon slips down and covers more of the abdomen than of the chest. Other applications are of less value. Blisters are not proper treatment for infants, in my opinion, and are not indicated in older children. Rubefacients, such as turpentine and mustard, are of value in bronchial catarrhs following pneumonia, or occurring independently of it, rather than in the pneumonic process itself. Dry cups may sometimes be of service. The use of ice or of ice-water compresses on the chest is a valuable procedure where there is much pain, particularly if the fever is high, since it acts as an antipyretic as well.

The treatment of fever in pneumonia is an interesting subject. Ten years ago the medical world acted on the principle that high temperature, by whatever caused, ought to be reduced at all hazards. Now there is a tendency to let the fever take care of itself. Whether or not high temperature is to be treated depends altogether upon the individual case. If convulsions are threatening, or actually going on, and we have reason to believe that they are due to hyperpyrexia, no time should be lost and the temperature should be lowered at once. So also if a child is restless and uncomfortable, as a result of high fever, the temperature should be reduced. Again, if the temperature in bronchopneumonia is persistently high, and we have reason to fear the action upon the tissues of such continued elevation, it is proper to take measures to alter the condition. But to treat fever simply because it is fever, is, I think, a mistaken policy. How the temperature shall be reduced is the question which naturally arises. Ten years ago every one turned at once to the internal antipyretics. Now the tendency is to decry them in a wholesale manner as harmful. As with nearly everything else, the truth, it seems to me, lies in a middle course. I have seen the whole aspect of a case changed and impending convulsions aborted by the administration to a child of a drug of the coal-tar antipyretic series. In my experience, children bear these drugs, as a rule, remarkably well; better than adults do. A series of observations upon the use of these drugs in children, which I published two or three years ago,[1] thoroughly convinced me of their value in properly selected cases. As a rule, however, I think that hydrotherapeutic measures are to be preferred. Sponging is of great service, and the tepid tub-bath is invaluable for reducing fever and allaying nervousness in children. It will act efficiently, when water of the same temperature would have failed in adults. Where this does not succeed we should not hesitate to proceed to the use of the cold tub-bath, exactly as in typhoid fever. It is a mistaken idea that the cold bath must not be used because we are dealing with an inflammatory disease of the chest. I have repeatedly used the cold bath, both in adults and children suffering with pneumonia, and never with bad results. Here again, the nervous symptoms are more a guide for its use than is the mere elevation of temperature.

In this connection I may speak of the hot bath; not used for any action upon temperature, but for its surprising influence upon the general state, and especially on the dyspnea. In the case of children, especially infants, who are extremely dyspneic, cyanosed, pallid, and apparently nearing death, a plunge into a hot bath of 105° or 110° often causes a vigorous reaction with renewed respiratory power. The child should be kept in the bath from three to at the most five minutes, and then wrapped in blankets. I was sent for by a physician living in New Jersey to see his baby, ill with pneumonia. The child's condition was as I have described. I advocated a hot bath, which the father was almost afraid to give, since the state of the child was so very low. While admitting that the procedure seemed rough, and was not devoid of danger, I still urged that death would certainly take place soon unless some change could be brought about. The effect was excellent. The blue color disappeared, and the natural color returned; respiration was made greatly easier, and the other symptoms were correspondingly improved. The baths were given repeatedly during the illness, and I think they would have succeeded in saving the child's life had I not reason to believe, from subsequent events, that the case was one of tubercular bronchopneumonia and consequently hopeless. This treatment with the hot plunge-bath is good, I may say, for other conditions where death seems imminent from failure of respiration, as, for instance, in atelectasis, and I have seen children recover who were apparently moribund.

The antitoxin described by the brothers Klemperer was hailed with enthusiasm, but has not obtained a foothold. The few cases in adults in which I have studied its action were not helped by it.

[1] *Archives of Pediatrics.*

There is no one line of treatment which can be followed out in every case. The physician who says that he treats pneumonia in this or that way, as though it were some harmful beast to be slain in some definite manner, falls far short of a true understanding of his subject and of his duties to his patient. What drugs we shall select depends entirely upon circumstances. In some instances aconite seems to be of distinct value, especially early in the disease; yet it is a medicine which must be used with care. I have thought that I got good results from aconite especially in children. Digitalis is certainly of service in many cases, yet caution must be observed not to drive the heart too much. Alcohol is a standby whenever we fear failure of the vital powers. Strychnin is useful for the same purpose, and as a respiratory stimulant as well, and may be given in large doses to children in suitable cases. There prevails, to some extent, an ill-founded fear of opium. It is a drug of extreme value in many instances, yet one which must be used carefully, especially where the patient has any increasing tendency to apathy or mental dulness. Under such conditions, it is hardly safe to give it at all to children. Ammonium carbonate is a disagreeable drug, but one which seems to be useful in some instances. It is not now, however, viewed as the proper routine treatment, as it once was. I myself give it comparatively seldom. Ammonium chlorid has seemed to me of service, particularly in bronchopneumonia, although some writers deny it any special value. In strong children, oppressed by a large secretion of mucus, an emetic of ipecacuanha often gives great relief, but it is only exceptionally that it is indicated. The use of vapor, especially under a tent of blankets, is sometimes of much service, when dyspnea is urgent. The value of inhalations of oxygen for cyanosis is never to be forgotten.

LOCAL QUARANTINE.

By G. J. KAUMHEIMER, M.D.,
OF MILWAUKEE, WIS.;
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS; PHYSICIAN TO THE MILWAUKEE HOSPITAL.

THE general principles governing the local quarantine of contagious diseases in this State have been but recently reaffirmed by a circular of our Board of Health. I shall, therefore, content myself with a criticism of some of these regulations, and some suggestions looking toward their better administration and a lessening of the hardships sometimes following their execution.

What to quarantine.—This has been settled for us by the circular referred to. To the list[1] there given of contagious diseases, the writer would be glad to see added gonorrhea and syphilis. He is well aware, however, that this is possible only in the sanitary Utopia of the future.

Whooping-cough should certainly be placed upon the list of diseases which should be placarded. This disease is so little feared by the uneducated portion of the laity that very many cases are never seen by a physician until the occurrence of pneumonia, bronchitis, or other febrile complications alarms the relatives. As Dr. Sweemer pointed out to this Society a year ago, the mortality of this disease is greater than that of scarlatina. The great length of time during which the patient may infect others, and the necessity of allowing the children to exercise in the open air, render the enforcement of strict isolation particularly onerous and difficult. Perhaps the method in use in Germany to indicate the bearer of a fresh vaccine vesicle, a piece of colored cloth attached to the sleeve, might be employed.

Tuberculous patients, too, should be reported and put on the "suspicious list," to the extent of receiving instruction, supplementing that of the medical adviser, concerning the dangers of indiscriminate expectoration. A proper record of these patients would enable the authorities to enforce proper disinfection of all premises vacated by reason of their death or removal.

How to quarantine, and do it effectually, is a problem, which has not, as yet, been wholly solved. The usual method of placarding a house containing a case of contagious disease, is still looked upon, by altogether too large a portion of the laity, as a concession to a medical fetish. Officious and sympathetic neighbors will run in, and children not yet sick will be sent on errands or out to play, in spite of the admonitions of the medical adviser and health officer. It is difficult to prevent this without placing guards at each house, as was done during the recent smallpox-epidemic in Milwaukee. But here the financial specter lifts its warning hand.

Nor will the establishment of an isolation-hospital, however well appointed and managed, remedy the evil. Recent experience shows that a large portion of the populace will resist to the utmost the removal of patients to such an institution. Education, which requires time, seems to be the only remedy. The fear of loss of occupation, and consequent privation or destitution has,

[1] Asiatic cholera, yellow fever, smallpox, typhus fever, leprosy, bubonic plague, diphtheria, scarlet fever, typhoid fever, measles, rötheln, and whooping-cough.

in my experience, been the cause of delay in sending for a physician, with correspondingly increased opportunities for the dissemination of infection, and greater severity of the original case. The writer knows of several cases where great hardships were inflicted upon boarders, especially upon teachers, by an outbreak of contagious disease in their place of domicile. The fact that they came from an infected house debarred them from entrance into other boarding-places.

The establishment of a "House of Detention," to which such exposed persons could be taken, bathed, disinfected, and observed, until the period of quarantine had expired, would mitigate such hardships to a considerable degree. In the case of diseases whose cause is known, such as cholera or diphtheria, a bacteriological examination with negative result, could be followed by immediate discharge of the suspect after disinfection of the clothing, etc. In other diseases the suspect having been removed much earlier from contact with the disease, the "date of last exposure" would be much earlier, with a lessened liability of contracting the disease. The isolation of the sick from the well, in the workingman's cottage as well as in some more pretentious quarters, is not attempted for lack of room, nor can it be enforced where a tired, overworked mother is sole nurse and housekeeper. Here, again, the "House of Detention" would show its value. The members of the family remaining well could, after the expiration of the quarantine-period, be sent to relatives or boarded at the expense of the community until they could go home in safety.

In suggesting the establishment of a "House of Detention" (House of Observation, or Observation-hospital might be a less repellant title), I am well aware of the many objections, financial as well as social, which may be urged against it. While everybody would agree that it would be a very desirable thing, everyone would want it located at the other end of the town, and fight its location in his own neighborhood to the full extent of the law. Quarantine implies, as a necessary sequel, disinfection. A thorough and efficient disinfection, as we now understand the term, requires a large and expensive plant and trained help. The ordinary fumigation with sulphur is nothing but a fumigation, a smoking.

If you recall the scene you all have probably witnessed, where the entire surplus-stock of clothing had hung uncovered in the patient's room, and the exulting remark of the mother, that she had removed the best pieces before fumigation for fear the vapors would spoil them; and also recall the impossibility of penetrating mattresses and feather beds by vaporous antiseptics under atmospheric pressure, you can hardly be surprised that contagious diseases break out again and again. In order properly and thoroughly to disinfect an infected house, the furniture, and in fact all its contents, should be covered by, or packed in, carbolized sheets, and brought in closed wagons to a place where they can be subjected to the action of live steam under pressure. Meanwhile, the house could be fumigated with sulphur after wetting down the walls, then well aired and scrubbed, and the walls limewashed or repapered. Such a house could be again occupied with confidence and safety.

The question will be asked: Where will the patients and attendants go during this prolonged operation? I answer, to a department of this same observation-hospital, where they can undergo personal disinfection. In fact, such a house of refuge was proposed, if not actually built, in the city of Berlin some years ago. The city of Milwaukee has made a good beginning by the construction of a disinfecting van, in which infected articles can be subjected to live steam; but to my mind, anything less than the measures outlined above can hardly be called a thorough disinfection.

For the transportation of suspects and convalescents to and from the observation-hospital, the authorities should provide suitable vehicles capable of perfect disinfection. Stringent orders should be issued to teachers to insure the observance of rules of the circular referred to. This rule provides that school- and library-books shall not be taken into infected houses, or, if therein, shall be destroyed. No child should be allowed to enter school from an infected (disinfected) house unless provided with new books. Similar instructions should be issued, absolutely prohibiting teachers from sending children to a residence to ascertain the reason for the scholar's absence. This is done, I know, quite frequently in the city of Milwaukee, and its dangers need hardly be pointed out.

Cases of typhoid fever should receive a stricter surveillance from the health authorities than they have heretofore received. It is absolutely impossible to estimate the number of undisinfected typhoid stools thrown out by careless or overworked nurses, to find their way eventually into the water-supply. The authorities could greatly aid the family physician by frequent inspections and by supplying disinfectants at public expense if needed. In cases of cholera there is hardly

such danger that the attendant's advice will be neglected, the disease running a much shorter course, and the people fearing it much more.

The examination of travelers, their detention and isolation, if found open to suspicion, as well as the establishment of sanitary cordons and camps of observation and refuge, are so complicated by the operation of our triple system of laws, local, State, and national, that they are not within the purview of this paper.

DISINFECTION OF ROOMS AFTER CONTAGIOUS DISEASES.[1]

BY U. O. B. WINGATE, M.D.,
OF MILWAUKEE, WIS.;
SECRETARY STATE BOARD OF HEALTH, WISCONSIN; PROFESSOR DISEASES OF THE NERVOUS SYSTEM AND HYGIENE, WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS.

SINCE the acceptance of the germ-theory of disease, the word "disinfection" has taken on a somewhat different meaning. Before, it included the temporary removal of infectious matter and the suppression of noxious odors; now, a disinfectant must not only mask bad odors, but must kill the germs that give rise to them, and may well mean a germicide.

To disinfect a room after the existence of contagious disease therein means practically to destroy all of the pathogenic germs and their products that may exist in the room.

The following are the diseases termed "dangerous and contagious" in this State, requiring disinfection after their appearance, *viz.*, Asiatic cholera, smallpox, diphtheria (membranous croup), scarlet fever, typhoid fever, and tuberculosis. In other States, yellow fever and typhus fever, which do not exist in Wisconsin, are added to this list, and in some foreign countries bubonic plague. In some cities in this country, measles and cerebro-spinal meningitis are included among those diseases which require disinfection, and the English authorities so regard erysipelas, and relapsing, continued, and puerperal fevers.

The disease-germs supposed to cause cholera, diphtheria, typhoid fever, and tuberculosis have been isolated. However, disinfection seems to be as efficacious in those diseases where the germ has not been isolated, namely, smallpox and scarlet fever, as in those where it has.

To disinfect a room in which any of the aforesaid diseases has existed, as soon as the patient has been removed by recovery or death, no time should be lost in carrying out the process of disinfection decided upon. In the first place, all inexpensive articles of clothing, fabrics, etc., that are found in the room, should be burned. In the second place, all washable fabrics should be plunged into boiling water for at least a quarter of an hour. In the third place, all beds, mattresses, bolsters, pillows, carpets, rugs, stuffing of easy chairs, etc., should be packed up, if possible, in rubber receptacles or bags, and removed to a disinfectant station, where a thorough system of disinfection by steam can be conducted. These stations should exist in certain districts throughout the country, and in every city and large village.[1] It is utterly impossible to disinfect the aforesaid material satisfactorily by any other process known at the present time, than by submitting it to hot steam for from ten to fifteen minutes, which should come in contact with every portion of the article to be disinfected. Mattresses, pillows, bolsters, etc., should be opened before being subjected to the process. Fourth, the floor in the room should be washed with a 1–1000 corrosive-sublimate solution, care being taken to saturate the interspaces between boards, and the walls should be sprayed in like manner by a garden-syringe or similar apparatus. All crevices about the window-frames and sashes and doors should be thoroughly washed with this solution; also the furniture in the room, after the upholstering has been removed, or that which is not provided with upholstering. The ceiling should be limewashed, and special attention be paid to cornices and all ornamental work, that no part escape a thorough application. The papered walls should be bared, the paper being removed and burned, after which the walls should be thoroughly whitewashed before being repapered. All picture-frames and other articles having gilt frames, also fenders, fire-irons, and metal-work generally, which cannot be washed by corrosive sublimate, should be covered by a five-per-cent. carbolized vaselin and thoroughly wiped dry, or, in many instances, they may need only to be well polished. Of course, this does not apply to dishes, etc., of all descriptions, which may be boiled. The room should then be left with the windows open for a day or two, after which it is well to whitewash the ceiling and walls again and scrub the floors with soap and soda, which will convert any remaining sublimate into a non-volatile compound. A fresh coat of paint would be of further security.

[1] Read before the Wisconsin State Medical Society.

[1] It is unnecessary for me to go into the details of a disinfection-station, as information relative to this matter is in the possession of all who have given any attention to the subject, and it is now a recognized fact that such stations and apparatus can be put into operation at a comparatively low cost in any city or village, and their method of operation is so simple that any one with ordinary intelligence can soon learn to operate them.

It is to be borne in mind that pure air, and plenty of it, and sunlight are two of the most valuable germicides we have at the present time. They are almost always available, and should be utilized in every way and as long as possible in the process of disinfection.

I have no confidence in the use of sulphur[1] burned in rooms as a disinfectant for general use, inasmuch as it is impossible to carry out the necessary details in order to have it effectual. No doubt it is efficacious in instances where three pounds of sulphur can be burned in a moist atmosphere containing a space of 1000 cubic feet; but the room must be absolutely sealed from the invasion of air, which is a very difficult thing to obtain, as a general rule, and is, in a majority of instances, impracticable. We know that the bacilli of anthrax are exceedingly difficult to destroy, but Koch found that in an atmosphere containing one per cent. of sulphurous acid the bacilli died within one half-hour, but the spores resisted in an atmosphere containing six per cent. for days, although when spread on wet filter-paper, they were killed in an atmosphere containing five per cent. in twenty-four hours. In some instances, where no other means are obtainable, sulphur-fumes used as stated may be advisable, but are not to be recommended.

We know that the bacilli of diphtheria, typhoid fever, and tuberculosis are comparatively easily destroyed where they can be fully exposed. A great deal depends upon the care of the patient and room. By removing from the latter needless furniture, carefully destroying all effete matters thrown off by the former, and thus preventing the dissemination of these germs in the atmosphere surrounding the patient, disinfection, after the patient has been removed from the room, is rendered easy. But it must not be considered that the atmosphere is the dangerous element so much as articles of furniture, floors, ceilings, and walls of rooms. Professor Willoughby of London correctly states that "Aerial disinfection is a work of medieval superstition, a delusion, and a snare, satisfying ignorance and diverting the attention from really efficient methods of disinfection."

In typhoid fever we have some problems to contend with, not yet fully solved. It has been supposed that the entire danger of this disease was contained in the discharges from the alimentary canal, but recent observations have led us to suspect that the disease may be taken from the urine, the perspiration, and the respiration of the patient. This being the case, it is advisable not only to disinfect the discharges from the alimentary canal, which can best be done by having them deposited in a five-per-cent. solution of carbolic acid or in the milk of lime, but also that the bedding, floor, and perhaps wall and ceiling, and the furniture of the room should be disinfected, as in other germ-diseases. This is a matter, however, not yet fully developed.

Finally, it is well to remember that the most effective agents in disinfection are the cheapest, namely, corrosive sublimate, lime-wash, boiling water or steam, together with sunlight and pure air. It is very probable that experimental chemists may soon find other chemical agents of a germ-destroying character which will be more efficacious than any we now possess.

[1] If the reader will take the pains to refer to pages 277 and 495 of the present volume of the MEDICAL NEWS, he will be convinced by the report of Mr. Henry Kenwood's experiments that the fumes of burning sulphur are much more efficient and reliable than the author of this article seems willing to admit.—ED.

ROUTINE CLEANLINESS, ISOLATION, AND WATCHFULNESS OF SCHOOLS AND CHILDREN.[1]

BY SAMUEL H. FRIEND, M.D.,
OF MILWAUKEE, WIS.

DURING the past year my attention was called to the sanitary conditions existing in one of our public ward-schools. Upon inspection, I found such a palpable neglect of both routine cleanliness and building arrangements as would appear hardly possible at the present time, when the knowledge of both as infecting agents is so widespread. Briefly summarized, these abnormal conditions were as follows:

Under indications of a lack of routine cleanliness there were: In the basement, a wet floor under the urinals, the odor of which could be got upon entering the building; filthy seats to closets; dust and cobwebs sticking to the walls and ceilings. There were on the three stories above, dust-laden floors, more especially noted in the corners of stairways and schoolrooms; dirt upon walls, ceilings, desk-stands, desks, foot-boards, window-casings, sills and windows, with cobwebs here and there attached to the ceilings; filthy, greasy-looking slates; a single washstand on each floor, the iron basins of which were rusty, while the wooden casings were greasily dirt-stained, with no soap visible. Over each water-spigot was a single, filthy, rust-stained, tinned drinking-cup, hanging upon a rusty nail.

Under building arrangements I found: In the basement, closets and urinals exposed to dim daylight, and no sunlight; closed plumbing; wooden

[1] Read at the meeting of the Wisconsin State Medical Society.

floors; low ceilings; no arrangements for ventilation. On the upper flats the floors were of soft pine, much worn, and the joints were separated. Walls and ceilings were cracked and rough. There were no arrangements for ventilation save by opening windows.

With the exception of a small addition, the building was very old. From six hundred to eight hundred children and teachers were housed from 8.30 A.M. to 12 M., and from 1.30 P.M. to 4 P.M. each day. When consideration is given to the germ-carrying capacity of the clothing, shoes, hats, hands, hair, and saliva of the children attending this school, in many of whose homes diseases prevail, it is obvious that, with these unhygienic surroundings, whenever there is an infectious disease in this city, this school represents a large number of cases.

Taking the investigations of Schiller, Cornelly, and Foggie, Brown-Séquard and D'Arsonval, Mitchell, Billings, Bergey, and many others as guides, everything indicates that far more insidious unhygienic conditions exist in our schools than in hospitals. This is especially apparent in general class-rooms wherein, irrespective of location of homes and their internal cleanliness, all children are aggregated according to advancement in learning. The result is that they, and all persons with whom they may come in contact, have only the individual resistance of the cell as a protection. This resistance, or range of bactericidal force of the cell, may be so abnormally limited by the struggle between hereditary biological phenomena and forced acquirements that it cannot protect itself against the microörganisms present.

As we know, hospitals are now systematized so that buildings and wards are specialized. Every detail of clothing, bedding, etc., is rigidly guarded. From the researches of Leewenhoek, Hunter, Jenner, Huxley, Tyndall, Pasteur, Lister, Koch, and Semmelweis, we have learned methods for preventing the spread of infectious diseases. We apply them in our most detailed practices. The preceding pages indicate the necessity of their minute application in schools. Then why do we not apply them there?

With the desire of advocating reforms in schools, I have made inquiries at the various orphan asylums and other institutions in this city, and I have consulted such literature as is at hand, to ascertain the character and frequency of contagious diseases. The uniform information is that such diseases are less frequent and in a diminished proportion to the numbers of children housed and confined during certain hours, as in schools. These facts point strongly to three systematic methods of living, when consideration is given to hereditary predispositions, such as are presented in children living in orphan asylums. They are: Stringent routine cleanliness, isolation, and espionage or watchfulness.

As another reason for these reforms in schools, I need only quote the precautions of physician, surgeon, and nurse in the operating and obstetrical rooms. It is only necessary to mention the investigations of Fraenkel, Cornet, Manfredi, and many others in order to justify extreme precautionary measures. A further fact which should demand these reforms is that in most cities in this country the position of health commissioner is a political office, and as a consequence appointments are made only because of a "pull," and irrespective of fitness. If, perchance, the health officer is fitted for the work by virtue of a knowl edge of minute and detailed technical hygienic requirements, then he is hampered in doing his duty by a lay board of aldermen, who virtually dictate his policy. Such a condition of affairs makes the proper watchfulness of contagious diseases almost an impossibility, and as a consequence it is not uncommon to hear of children attending school when one or more members in the family have some contagious disease. This is in part also owing to a certain carelessness in the physician in not reporting such cases.

From these facts, the indications are that the biological resistance of the cell is being primarily limited by the action of the faulty ventilation, combined with the discipline necessary to impress the acquirements of our present civilization. The result is, that the lack of routine cleanliness and watchfulness of the homes and schoolhouses causes the children to carry into and accumulate in both innumerable pathogenic germs, which find a ready medium for further evolution in the weakened cell.

The problems to be solved, then, arrange themselves under two headings:

(1) To devise systems of education which do not enervate the child by limiting accommodation and bactericidal force, and (2) to use compensatory measures against the accumulation of pathogenic germs in the houses, the schools, and upon the clothing, shoes, hands, etc., of the children. Time alone will solve the first. From preceding evidence, the second may be accomplished by (1) stringent rules governing the architecture of school-buildings and their routine cleanliness; routine use of soap and water for exposed parts of the body—face and hands, and (2) by the use

in the schoolroom and during school-hours of outer garments, which will cover the clothing worn, and, as a consequence, isolate pupil from pupil, and persons in general from the pathogenic germs clinging to ordinary clothing. The stuff for such garments for both foot- and body-wear could be made of very inexpensive material. Every school should be compelled to place in some part of every school-building a sterilizer, so that these outer garments (devised and made as best suits the condition to be met) can be surgically cleaned each day and made a part of the routine cleanliness, as is the sweeping of floors, etc. These garments can be tagged, lettered, or numbered, and placed in lockers for daily use. As suggested by Cohn and adopted in most European countries, "a qualified hygienist, having a special diploma stating his fitness," should be made an advisor of the school-board and have supervision of the hygiene of schools. The health-commissionership should be a non-partisan appointment—fitness alone determining a choice.

In closing, I would call the attention of the members of this society to the use in schools of the pernicious feather duster which simply displaces dust, and I would suggest in substitution the use of damp gauze, which catches all dust, and, on account of its cheapness, could be burned, or, if desired for further use, could be sterilized.

AN ADDRESS.

THE HOSPITAL AND DISPENSARY ABUSE.[1]

BY LANDON CARTER GRAY, M.D.,
OF NEW YORK;
PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE NEW YORK POLYCLINIC.

WHEN I look over the long list of presidents of this Society, and perceive such names as Hosack, Cock, the two Rogers, Delafield, Bulkley, Taylor, Finnell, Hubbard, Peasley, the two Elliotts, Jacobi, Sands, Peters, Bumstead, Purdy, Sturgis, Webster, Vanderpoel, Lewis, Grandin, and Fisher, I cannot but feel that I have received a great honor in being chosen as a successor to these gentlemen.

In the great changes that have taken place in this city between 1806, when this body first came into existence and the population was about 90,000, and the present year, during which it is estimated that the dwellers within our corporate limits number 1,851,060, medical societies have multiplied, not only for scientific, but also for social, topographical, and collegiate reasons, and the County Society no longer occupies the same relative position that it did for years after its foundation; and this has too often caused those not familiar with its work to overlook the fact that it is possessed of great powers, which would make medical men instinctively turn to it as an arm of strength in time of trouble or epidemic. It has at the present time a membership of 1484. It is the official or representative society of the medical profession in the county of New York; while, through its delegates, who can become members of the State Society by the simple process of attending for two successive years, it has an intimate affiliation with the larger organization, and by this intermediary, with every county medical society in the State. It has three standing committees of great importance. By means of the one upon Ethics it regulates the professional conduct of its members with an authority that very few men would care to dispute. By its committee on Hygiene it keeps watch over the public health, and the committee upon Prize Essays gives an opportunity for generous recognition to many a struggling man of talent. It has a large and active Comitia Minora, acting as councilors to the President. It has a salaried legal counsel standing ready to protect the interests of the profession against imposture and injudicious legislation. It is in the metropolis, and its incentives, its opportunity, and its dignity are that of the greatest city of the country, so that what it does (provided it be worthy of notice) is known of all physicians throughout the broad American nation. I do not need to remind you how effectively these powers have been used in the past and are being employed in the present, for the historian of the battles that have been fought and won here for a higher standard in medicine, would need more than an evening to chronicle them.

It would seem, from what information is at my disposal that the members of this Society are not aware of the fact that Section 41 of the Consolidation Act, Chapter 410, Laws of 1892, disqualifies a physician from being the president of the municipal Board of Health in these words:

"The head of the health department shall be called the board of health. Said board shall consist of the president of the board of police, the health officer of the port, and two officers, one of whom shall have been a practising physician for not less than five years preceding his appointment. The commissioner of health, who is not a physician, shall be the president of the board, and shall be so designated in his appointment. The commissioners of health shall, unless sooner removed, respectively hold their offices for six years, and until their successors shall be respectively appointed and have qualified."

I am told that this clause was copied from the Charter of 1873, but I am at a loss to understand the reason for the disqualification of physicians for an office peculiarly requiring medical skill and experience.

But I ask your especial attention to-night to the abuse of medical charity—a subject which has been so often discussed and rediscussed that our souls have become weary, and I should hesitate to allude to it but for the seeming opportunity now offered to us in the power recently given to the State Board of Charities to revoke the charter of any institution proven to dispense medical charity improperly. This clause was introduced into the new Consti-

[1] Inaugural address of the President-elect of the New York County Medical Society, delivered at the annual meeting, November 23, 1896.

tution by Mr. Tunis G. Bergen, president of the State Board of Charities, to whom the profession is under a lasting debt of gratitude; and I never fully appreciated what this gentleman has attempted to do for us until I obtained accurate figures upon the subject, through the kindness of our distinguished colleague, Dr. Stephen Smith, who is a most energetic member of the same board. From these statistics it appears that the county of New York has at the present time twenty-six hospitals and 114 dispensaries. In the former, during 1895, 75,368 patients have been treated free, and in the latter 661,803, making a total of 737,171. The population of this city is only 1,851,060, so that the proportion of such free patients to the whole community is thirty-nine per cent. There have been 92,529 free visits of patients to hospitals in 1895, and 1,387,170 free visits of patients to dispensaries. Out of 1,104,381 prescriptions that have been dispensed there is no means of knowing exactly how many have been without charge, because fifty-two of the dispensaries have made no report to the State Board of Charities, while of the sixty-two that have reported, sixteen make no charge for their medicine, and forty-six make nominal charges of from five to fifty cents, or nothing when the patients are unable to pay. Of these 114 dispensaries, sixty take certain precautions to weed out the unworthy, such as making inquiries, questioning the patients, judging by their appearance, and by the statements of physicians sending them, while the remaining fifty-four either make no inquiries or have made no report. In attendance upon these 114 dispensaries are 949 medical men, which is twenty-seven per cent. of all the physicians in the city, who number 3430. Efforts were made to ascertain how many of these patients were non-residents, but the answers were usually very indefinite; one institution stating "Very few, if any," others "from one to ten per cent.," while ten had treated 2124. The foregoing summary does not include institutions under the charge of the local Commissioners of Charity, one of whom, Mr. John P. Faure, has kindly informed me that there are eight city hospitals, containing 7089 patients, and that the out-patient branch has treated 49,620 patients during the year ending June 30, 1895. Although it is probable that these cases are really worthy of charity, yet, in strict logic, the figures should be added to those given above, which would swell the total of patients treated in this city in one year to 793,880.

These statistics confirm the rumors that have been rife among us for many years, such as that the president of one of the largest municipal railroad corporations was discovered to be a regular attendant at one of the dispensaries; that patients come occasionally to the clinics in carriages; that practices can almost always be obtained from certain clinics in a large dispensary, such as those of general medicine or gynecology; that the neighborhood of large dispensaries is bare of physicians' residences; that patients come to town from distant cities with a physician, occasionally with a relative, put up at a hotel, seek a clinic for medical advice, and when told in one dispensary that they are not fit objects of charity, speed away in hot indignation to another; that patients are frequently sent to a clinic with a letter from the attending physician containing a modest request for diagnosis, prognosis, and treatment, inquiry eliciting that their intention is to go back to this gentleman's office and pay him for treatment; that patients in the country towns for miles around New York are quite appreciative of the excellencies of our city dispensaries for different diseases; and that patients constantly go to dispensaries in order to ascertain the best physician for their particular disease. The reason for the enormous increase in our charity work is plain to any one who has witnessed the development of our hospitals and dispensaries of late years. The public must be appealed to for money; the larger the number of patients, the more need shown for money; and no effective general regulations being strongly enforced, the growth of the abuse has been so stupendous that all methods of restriction have proved utterly ineffectual. The intentions have been altruistic in the extreme, on the part of both lay and medical members of hospital boards; indeed, it is questionable whether any one has known the full extent of the evil.

It will not be denied for one moment that a certain, nay, a liberal amount of charity work is a necessity to the medical profession, distinguishing it in this respect from all others. The lawyer, for instance, the engineer, the minister, the architect, the *littérateur*, the journalist, can each perfect himself in the art of his calling without proffering his services gratuitously. But the physician must study types of disease only to be adequately observed in sufficiently large numbers either in a very large practice or in hospitals and dispensaries—indeed, it may be doubted whether the fullest practice, in the harvest-time of a successful physician's life, can offer him such opportunities for familiarizing himself with maladies as do our hospitals and dispensaries. It must be remembered, too, that relatively few men obtain great practices, and that they can only hold them by means of the knowledge of ailments acquired in the previous years of attendance upon hospitals and dispensaries. So that these institutions are the training-schools of our profession, inestimable to the men whom they bring into contact with each other in their varyingly eager and mutually stimulating pursuit of the same ideal, aided by the assistants, the instruments, the nurses, the housing, and the organization of such corporations. Then, the thousands of students who come to this city must be taught, and this cannot be done without the clinical material of hospitals and dispensaries. Any unwise restraint would therefore imperil the existence of New York as the medical center of the country, and no man in his senses would dream of such restriction. But such manifestly indiscriminate charity as exists does not seem necessary to these purposes. It is trite to say that no suffering person should fail to receive the medical aid that may be needed in the emergencies of life, but in this city there really does not seem to be much likelihood of such a grievance, when 949 physicians, out of a total of 3430, treated 737,171 patients in one year, made 1,479,609 free visits, and wrote 1,104,381 prescriptions, besides paying due attention to the other duties incidental to attendance upon twenty-six hospitals and 114 dispensaries.

In our medical profession there are gentlemen who

have been so favored by fortune that it has not been their lot to come in contact with the seamy side of practice; there are others to whom fame has brought its attendant success; there are still others whose special branches obviate the necessity of general practice. To these medical men this statement of facts may seem exaggerated, but the great body of practitioners, and those who are broad-minded enough to realize this grave violation of the first principles of a wholesome political economy, will feel, as I do, that prompt and just measures should be taken to regulate our medical charities. For my part, I have a most thorough appreciation of the needs of those upon whom we should bestow charity, but my sympathy is broad enough to embrace the medical as well as the lay poor. I therefore recommend to this Society that a special committee be appointed to obtain such facts about this subject as may be necessary to just conclusions, and that the results of this investigation be submitted to the entire Society for such action as it may think proper. I would suggest that this committee consist of eleven members, namely: the chairman, five members to represent respectively the five medical schools, and the other five on behalf of the profession in general.

CLINICAL MEMORANDA.

A CASE OF EXSECTION OF THE RECTUM BY THE VAGINAL ROUTE.

By A. T. BRISTOW, M.D.,
of Brooklyn;
Surgeon to the Long Island Hospital; St. John's Hospital.

The operation of exsection of the rectum, whether in male or female, ought to be restricted to those cases in which it is possible to get well above the growth which must not have invaded neighboring tissues. The old route by the perineum neither gave the requisite room for operation on any but growths quite low down, nor did it give the same opportunity for dealing with hemorrhage that later operations have done. The more modern methods of Kraske, Rydgaier, Bardenheur, *et al.*, secure the room which a high exsection requires by resecting the sacrum below the third sacral foramen, either transversely or laterally. In this manner it is possible to resect the entire rectum, and at the same time control the hemorrhage, always profuse, in a much more satisfactory way than after the old operation. The mortality of the operation is high, however, averaging in the hands of the best operators twenty-three per cent. In the hands of surgeons in general the mortality will be higher still. No doubt so severe a proceeding as resection of the sacrum must add to the gravity of the procedure, and yet in the male this can never be avoided, as in no other way can the necessary room be secured which a complete operation requires. My attention was called to a method of operating in the female by a reference in an article of Gerster's, appearing in the October number of the *Annals of Surgery*, to two cases of exsection of the rectum *per vaginam*. Two operators in Europe, Rehn of Frankfort, and Campenon of France, had removed the rectum in the female by this method. The method seemed to me feasible and to possess certain advantages over the sacral route, so that I determined to try it if a suitable case presented itself. The operation which I am about to describe is the third on record up to date, and so far as I know has not been done by any other operator in this country. Since writing the above Byford has reported a case in the *Annals of Surgery* for November, '96.

Case.—October 31, 1895, there entered my service in St. John's Hospital, J. E. W., spinster, aged fifty-seven. Two years ago she began to have pain in the abdomen, localized afterward in the rectum, especially severe on defecation. She passes much pus and blood, and fecal matter in tape-like strips. Examination discloses a tumor as high as the finger can reach. The vagina seems clear of growth. A diagnosis of rectal carcinoma was made, and one week later inguinal colotomy was done after Maydl's method. This gave the patient much comfort, and she began to gain in weight and was relieved of pain. Her condition continuing to improve, it was determined to attempt extirpation of the growth by the vaginal route. This was done on January 11, 1896. A median incision was made in the rectovaginal septum, from cervix to perineum, through which the bowel was enucleated without much trouble after the division of the levator-ani fibers, and the clearance of the bowel at the anal outlet. The hemorrhoidal arteries were recognized and tied in the course of the dissection, and the bleeding was easily controlled, that which gave the most, and, indeed, the only trouble, coming from the vaginal cut. After severing the levator-fibers the bowel was enucleated with the finger. Although this was a virgin vagina the rectum was easily accessible, and six inches of bowel were removed, the end remaining being stitched into the wound after being brought down as low as possible. The vaginal wound was sutured, as it was believed that the artificial anus in the groin would be less disagreeable to the patient, safer against recurrence as removing all sources of irritation from the original seat of the disease, and more easily taken care of. The patient made a good recovery from the operation. A few months afterward, however, the disease recurred, and the pelvis is now hopelessly involved. The method gives easy access to six inches of rectum without the shock of a sacral resection. Further than six inches it is not possible to go, judging from my experience in this case.

DELAYED UNION OF FRACTURED TIBIA DUE TO PREGNANCY.

By J. HERBERT DAREY, A.M., M.D.,
of Northwood, Iowa;
Fellow of the American Academy of Medicine.

On May 20th, 1891, I was called to see Mrs. D., who had been watching her husband fishing in the moonlight, below a mill-dam. While stepping on the slimy logs of the apron of the dam, she slipped, and fractured her right tibia about the middle of the shaft. The patient was the same one, by the way, whom I reported in the *Montreal Medical Journal*, vol. xviii, p. 732, as having supernumerary breasts. I put the leg in a fracture-box, and kept it there for a week or ten days, till the swelling

had all subsided. Then I put it up in plaster of Paris. I took off the plaster-dressing about six weeks after the injury, and the limb seemed perfectly straight, and the fracture firmly united. I could not get any motion in it at any rate. I advised her to try and go about the house carefully with the aid of a crutch, and to try to use the leg as much as she could bear. In about a week she sent for me, saying that the leg was not firm and solid as it ought to be. On examination I found that there was defective union, and got considerable motion at the seat of fracture, by firm pressure. I forcibly rubbed the broken ends together, and put the leg up in plaster of Paris a second time, feeling considerably chagrined at the non-union, which I could not account for in any way. I left the plaster-dressing on for six weeks more before I took it off. The leg was straight and in good position, but still there was non-union. I was completely puzzled by this state of things in a strong, healthy countrywoman, about thirty-five years of age, who had never had any serious sickness in her life, and was apparently in the best of health at the time. I soon heard from some of the neighbors that Mrs. D. was pregnant, which seemed to me to furnish a possible explanation of the non-union. On investigation, she admitted that she was three months pregnant at the time of the accident, and was by this time about six months advanced. She was a stout, fat, heavily built woman, with a pendulous abdomen, and I never had noticed any particular change in her shape. I now told her that there was no use doing anything further till the child was born. There was some motion, but the fibula acted as a good splint, so I told her to be very careful with her leg, and allowed her to go about the house with her knee on a chair. In this way she managed to do all her housework for a family of six or seven children till she was confined at full term. After her confinement, without any further treatment, the tibia united firmly, and now that leg is just as sound as the other one. The only explanation of this that occurs to me is that the osteogenetic elements of her blood went to form the fetal skeleton, instead of healing the fracture of the tibia. That this explanation is correct, is proved by the subsequent history of the case, and the rapid and permanent union of the fracture. I had never seen anything bearing on this subject in the text-books, nor have I ever read any similar case in the journals, and as it is a rare case, I desire to have it recorded.

MEDICAL PROGRESS.

Pseudo-bulbar Palsy of Cerebral Origin in Children.—As the result of a clinical study relating to involvement of the cerebral nerves in a series of cases of cerebral palsy in children, KOENIG (*Zeitschrift für klinische Medicin*, Bd. xxx, H. 3, 4, p. 285) has found that among the clinically atypical forms of cerebral diplegia there occur exceptional cases characterized by a prominence of the symptoms of bulbar paralysis, which may be designated the "pseudo-bulbar form of cerebral paralysis in children," or the "infantile form of pseudo-bulbar paralysis." In addition to this classic variety there occur masked forms characterized by the absence, or but slight manifestation, of difficulty in swallowing. Especially in such cases is great care required in the interpretation of the speech-disturbance, as a slight degree of nasal speech may be due to the existence, past or present, of adenoid growths in the naso-pharynx, or, more commonly, to a general relaxation of the entire muscular apparatus, in which the veil of the palate participates. There is, however, a group of cases in which speech, apart from its nasal character, is so distinctive as to be recognized as only of central origin.

Myelitis in a Choreic Child Following Treatment With Arsenic.—At a recent meeting of the Société Médicale des Hôpitaux, COMBY (*Presse Medicale*, 1896, No. 52, cclx) reported the case of a girl, seven years old, without rheumatic or cardiopathic antecedents, who came under observation about a week after the onset of a severe attack of chorea. Treatment was begun with the administration daily of the equivalent of $\frac{1}{7}$ grain of arsenious acid, the dose being increased daily $\frac{1}{14}$ grain, until it equaled $\frac{1}{2}$ a grain, and then being reduced in the same manner to $\frac{1}{7}$ grain. In this way $3\frac{1}{2}$ grains of arsenious acid were given in the course of eleven days. After the fifth day the choreic movements ceased, and did not return. On the sixth day vomiting occurred, the tongue was coated and slight febrile movement set in. After ten or twelve days the gastric disturbance disappeared, and the patient left the hospital. In five weeks, however, she returned, having been paraplegic for a week. The general condition otherwise was quite good; from having been pale and emaciated the child had become ruddy and full. The paralysis of the lower extremities was complete and the reflexes were abolished, but sensibility was unaffected, and there was an absence of trophic disturbance. In spite of treatment with strychnia, faradization, and sulphurous baths, the paralysis ascended to the trunk and the upper extremities, although in less degree than in the lower. Subsequently there was for a period of ten days incontinence of urine and feces. Finally improvement set in, and progressed in the inverse order of the invasion; and in the course of rather more than a month had advanced to complete recovery. The symptoms in this case are attributed to a myelitis of arsenical origin.

Cholecysto-bronchial Fistula, with Expulsion of a Gall-stone.—VISSERING (*Münchener Medicinische Wochenschrift*, 1896, No. 24, p. 567) has reported the case of a fairly well-nourished man, sixty-three years old, who had complained for two days of a sense of pressure in the epigastrium, loss of appetite and constipation. On the following day the patient was seized with a severe chill, attended with intense pain in the abdomen, particularly in the right iliac region, and obstinate vomiting. Perspiration was free, while the skin felt cold and the pulse was scarcely appreciable. The abdomen was moderately distended. A diagnosis of perityphlitis was made, poultices were applied locally, and opium was administered internally. The active symptoms ameliorated, but the liver increased in size, and became the seat of pain. Subsequently jaundice developed, and the stools were clay-colored, while the urine contained biliary coloring-matters.

In the further progress of the case the gall-bladder also became evidently distended, while the general condition of the patient grew gradually worse. The temperature fluctuated slightly above the normal, the pulse varied in frequency and size, and the respiration was accelerated. In the course of a month chills recurred, with elevation of temperature and dyspnea, and the signs of right-sided pleurisy. At the same time diminution in the size of the liver and of the gall-bladder appeared to take place, with lessening of the pain, The expectoration had by this time become copious and offensive; it was at first purulent, but soon presented an ocher-yellow, and the patient complained that its taste was as bitter as gall. This peculiarity of the expectorated matters was repeated from time to time, always with some diminution of the jaundice. Finally the diagnosis of a fistulous communication between the gall-bladder and the bronchial apparatus was confirmed by the expectoration of a gall-stone as large as a pea. The patient declined operative interference.

A Report of 105 Deliveries of Women With Contracted Pelves.—As a result of the study of the labor in 105 cases of contracted pelvis among a total of 4289 cases of all kinds under observation at the German Obstetric Clinic of the University of Prague, between the years 1891 and 1895, KNAPP (*Archiv für Gynäkologie*, B. 51, H. 3, p. 483) has reached the following conclusions: In proportion to the reports of other clinics the number of contracted pelves has been small. Flat and generally contracted pelves, without demonstrable evidences of rachitis, appear to preponderate over deformities due to rachitis; although it is not to be denied that at least one-half of all pelvic deformities can be attributed to rachitis, as this affection is by no means uncommon among Bohemian women. Among the whole number of cases osteomalacia was observed in but five; all happened to occur in one year (1895); but there was no relation between this fact and place of residence. Bohemian women, in general robust, usually presented with contracted pelves slender skeletons—especially was this so of primiparæ. The uterine contractions were, with individual exceptions, commensurate. Premature rupture of the amnion protracted the labor in most cases, and occurred more commonly in connection with contracted pelves than with normal. Expectant treatment was generally sufficient in most cases, both for mother and child. In regard to morbidity operative interference yielded for the mothers more favorable results than expectancy, and the reverse for the children. The complete results among the 105 cases were exceedingly favorable among the mothers; a mortality of 0.95 per cent.; but not so among the children—31.43 per cent. These results are attributable to the rule observed to place the greater importance upon the life of the mother.

Skiagraphy Applied to the Study of Akromegaly.—MARIE has described two types of akromegaly—the ordinary massive form and the giant form, which develop in accordance with the period of life at which the disease makes its appearance. Thus, if the disorder begins during the period of active growth, when the bodies of the bones, as well as the epiphyses, are capable of enlargement, the giant form usually results; whereas, if the disease begins after bone-growth has been completed, the massive form is likely to result. MARINESCO (*Compt. rend. heb. des Sciences de la Soc. de Biologie*, 1896, No. 21, p. 615) secured skiagraphs in three cases of akromegaly of the common massive type, and in one of giant variety. The first of the cases was in a man fifty-five years old, in whom the disease had been present for eleven years. Metacarpus and phalanges were uniformly enlarged, the increase representing merely an exaggeration of the normal. In another patient, thirty-three years old, presenting the aspect of a giant, the disease had begun about eight years before. The increase in size in this instance was rather in the direction of length, and the soft parts did not take part in the enlargement to the same degree as in the other type of the disease. Another patient, thirty-three years old, in whom the disease had existed for not less than seven years, presented, contrary to the accepted explanation, the massive type of the disease. In him the extremities of the bones were especially involved, and the circumference rather than the length. In the fourth case, occurring in a woman fifty-four years old, and of the massive type, the disease had been present for nine years, and was not well developed. The nose was especially enlarged. The bony lesions corresponded with those found in the other two cases of similar kind. Skiagraphs from a case of erythromegalia failed to disclose any skeletal alterations, an observation confirmatory of the view that this affection has no relation with akromegaly. In all of the cases of akromegaly the lateral aspect of the last phalanges appeared to be excavated, probably as a result of the very considerable enlargement of the epiphyses of these bones.

THERAPEUTIC NOTES.

Nitroglycerin in Angina Pectoris.—SCHOTT (*Wiener klin. Rundschau*, September 6, 1896) advocates the following prescription as the most efficacious form of administering nitroglycerin in angina pectoris:

℞ Nitroglycerin . . . . . gr. iij
Tinct. capici . . . . . ʒ ss
Spir. rectificat } aa . . . ʒ iij
Aq. menth. pip. }
Sig. 2–10 drops.

In one minute the action of the drug is manifest, and in scarcely three minutes the pain is entirely done away with. As the patient grows accustomed to the dose, it must be increased, and if this be done carefully there is no great danger to be anticipated.

To Prevent Baldness.—The following prescription is in use in the Dermatological Clinic in Vienna to prevent the hair from falling out:

℞ Tr. cinchona rubræ . . . . ℥ i
" cantharidis . . . . ʒ ss
Ac. carbolici . . . . . ʒ ss
Strych. sulph. . . . . gr. ij
Eau de Cologne } aa . . q. s. *ad.* ℥ iv
Olei cocos }

One or two applications *per diem* are required.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, DECEMBER 5, 1896.

ULCERATIVE ENDOCARDITIS SUCCESSFULLY TREATED BY ANTISTREPTOCOCCIC SERUM.

THE serum-treatment of disease is being constantly extended and with steadily increasing confidence in its efficacy.

Dr. Sainsbury, at the Royal Free Hospital, London, had the case of a lad, aged thirteen years, who had both renal and cardiac disease with febrile and other symptoms confirmatory of the diagnosis of malignant endocarditis. A treatment by injection of an antistreptococcic serum, beginning with a dose of 20 c.c., and continuing at half that dose, 70 c.c. in all being administered, was adopted. The disease, in the opinion of Dr. Sainsbury, as reported in the *Lancet*, London, October 17th, responded so promptly and satisfactorily to the serum-treatment that no apology is needed for recording it. Before the injections were commenced the patient had lapsed into a condition of marked cachexia; within two or three days the improvement in the aspect and bearing of the boy was unmistakable—he was clearer-looking, brighter, and the desquamating skin cleaned rapidly. Neither local reaction at the site of the puncture, nor any general reaction was observed except on September 1st, the time of the last injection, when the sudden rise in temperature, the general appearance of illness, and the pain at the site of the injection, followed so speedily upon the treatment, that there seemed no other explanation for the symptoms than the dose of serum. The boy, however, soon rallied, and then, curiously, took a fresh start; his temperature for the first time became normal, and his advance was then so rapid and uninterrupted that there was no excuse for another injection. Thus all the injections were markedly effective, but most so this last injection, which produced definite local and general symptoms. Was this reaction an unnecessary concomitant—the result of a by-product, or was it to be regarded as of the nature of a curative reaction?

In a recent case of ulcerative endocarditis at the Victoria Park Hospital for Chest-diseases, the antistreptococcic serum failed to arrest the disease, and seemed to have no beneficial effects; in this case, however, there was, in addition to the endocarditis, grave kidney-disease with cortical destruction, which may account for the failure; the disease was, moreover, in a more advanced stage, and of more virulent type.

THE CULLINGWORTH MALPRACTICE SUIT.

A SUIT for malpractice has recently been decided in England, which involves points of great practical importance, and deserves the serious attention of every active surgeon. The questions at issue were of vital concern to the patient on the one hand, and to the surgeon on the other. Plainly stated, they may be considered as follows: Has a patient, who is in full possession of his faculties, and about to undergo a surgical operation, the right to set the limits to that operation? And is a surgeon, who has advised and undertaken a definite operation, justified in extending the procedure, even to the removal of organs, not previously mentioned, if, in the course of the operation, he deems it vastly to the best interest of his patient so to do?

The case in question may be briefly stated thus: A trained nurse, who suffered from pelvic trouble, consulted Dr. Cullingworth of London

regarding her ailment. Upon examination, he discovered a swelling in the pelvis, which he diagnosed as an inflamed cyst of the right ovary. This he made known to the patient, and, in response to her inquiries, informed her that the left ovary was probably healthy, but it was impossible to speak with certainty regarding it. If, however, upon examination after the abdominal section, it also proved to be diseased, he should use his discretion about removing it. To this complete castration she was violently opposed, and never positively consented, although the doctor insisted that, while he would respect her wishes, she should leave the matter in his hands. By finally accepting the operation, the operator inferred that she had relinquished her objections.

From the evidence, it appears that Dr. Cullingworth took great care to explain to the patient what the remote effect of the operation would be: that if only one ovary were removed it would be quite possible for her to become a mother, but if both ovaries were sacrificed sterility must eventuate. Three separate and distinct interviews were held on the subject, and although the Doctor and the patient were directly at variance in their testimony before the court, the circumstances were corroborative of the statement of the former, to wit: that he could not bind himself by any promise not to remove the second ovary if it should prove necessary. From the pathological description of the organs, there was no question of the hopeless condition of the second ovary. The operator showed his consideration for the patient's wishes by endeavoring to dissect out the cystic portion of this ovary, and thus conserve the remainder, but his effort to leave healthy ovarian tissue was absolutely futile. The entire organ was thereupon removed. The case before the court became, therefore, simply an issue of veracity between the doctor and the patient regarding the previous understanding, and the jury lost no time in deciding positively in favor of the doctor. And the long, weary months of worry, anxiety, and persecution that he has endured for the sake of vindicating his position, and securing for it the support of the public is worthy of all praise.

Recurring now to the questions previously propounded, it may be said that the patient is the sole arbiter of his own life so long as he satisfies the canons of his belief in God and a hereafter, and does not offend the social and statute laws of his country. If he chooses, while in the possession of sound mind to take the chances with disease, although it may be contrary to the best professional judgment and advice for him to do so, no human being shall gainsay him the privilege.

On the other hand, the surgeon, when once he has entered upon an operation, has only the highest welfare of his patient and his own reputation at stake, both motives inciting him to do what is for the patient's best interest. Moreover, the patient can never be made to comprehend the vital importance of many technical procedures. Even after the fullest explanation, he is frequently confused or he wholly misunderstands. He must trust the details and the methods of meeting exigencies as they arise to the judgment of his medical adviser. Still, the unexpected that frequently arises in the course of an operation may be of serious import, and lead to the sacrifice of organs or parts of the body far beyond the anticipation of either surgeon or patient. The best interests of the patient will, therefore, be conserved if he places himself in the hands of the surgeon, trusting in his judgment to do what is best. But the only safety of the surgeon lies in securing the consent of his patient to that view of the case before the operation is begun. Indeed, it is a good rule of practice habitually to secure such consent.

Some surgeons go so far in this matter as never to undertake a serious operation without first securing the written consent of the patient to do whatever in their judgment they shall adjudge necessary. In operations on advanced cases of cancer of the breast it sometimes develops that the only hope of eradicating the disease and securing the prospect of a cure necessitates the amputation of the arm at the shoulder-joint. A similar experience often befalls the surgeon in operations for the relief of bone diseases. And yet few men would venture to carry these operations to their fullest extent without a previous understanding that their judgment was to be used and trusted.

THE "FUROR SCRIBENDI."

NEVER, for a corresponding period, in the history of medicine, has there been such a flood of technical literature as the last decade has produced. It is true that this decade has perhaps furnished more material than any that preceded it, but, even discounting this, there has been a veritable plethora of medical articles, monographs, and books. Foremost, perhaps, among the books we see a revival of the "systems;" a system of practice of medicine, of nervous diseases, of surgery, of gynecology, and so on. Doubtless this method is in a general way satisfactory, though it has many and serious defects. In the first place, the articles are notably uneven. This prevents the "system" from being an authority, at least to a great extent. The good and bad articles are somewhat indiscriminately sandwiched, and from a height of admiration of a good chapter we descend to the depths of despair at a very bad one. Then, too, some of the more ambitious "systems" require such a long time in their preparation that the first volumes frequently have the mild flavor of a back number before the last volumes are through the press.

The temptation for a college professor to write a book is apparently almost irresistible, and few men in our larger colleges have withstood it. The inducement for the college professor is obvious; it makes his teaching decidedly easier, and he has an admiring, and in many instances, a buying audience in his students, past and to come. Of course, in very many cases, the college professor is eminently fitted for book-making, but it by no means follows as a matter of course that because a man is a professor in a college he is competent to write a book.

Then the immense multitude of journal articles! A multitude that no man, except the editor of the *Index Medicus*, can number. Nearly every city in this country boasts one or more medical journals, and the death of one seems to be the signal for two or three new ones to rise phenixlike from its ashes. It is not clear whether the *furor scribendi* is a cause or an effect of the multiplicity of medical journals. While most of the important work appears first in the journals, still there is such an immense amount of trash that the really valuable papers are often obscured.

A duty which is much neglected in our medical colleges is the training of the student in scientific writing. When he gets into practice and is attacked by the *furor scribendi*, he is very prone to choose a large subject. He is prone to revel in "typhoid fever," the "treatment of pulmonary tuberculosis," or "Bright's disease." If, instead of doing this, he would confine his ambition to some limited field—for example, instead of disposing of the whole subject of typhoid fever he would take part of the subject, and discuss from the standpoint of his experience the eruption or the relapse, or some special symptom, his paper might be of value. Again, many valuable observations are obscured by the title. A "case of appendicitis" is usually passed over as one of no special interest, while in fact it may contain a point of great importance which is lost to the reader because it was not noted in the title. One who reads many journals gets into the habit, perhaps unconsciously, of passing over the papers on a general subject, unless he has reason to expect something from the particular author, and looks for special studies upon particular points. This concentration of work upon a limited area is what has made the monograph so valuable. If then the *furor scribendi* is to continue, and there is no indication of its subsidence, let it be directed to careful and accurate observation in a limited field. There are many men throughout the country who can, from time to time, furnish valuable microscopic bits, but it requires a master to make a subject interesting, macroscopically.

ECHOES AND NEWS.

An Epidemic of Scarlatina.—An epidemic of scarlatina attended with great mortality is raging throughout Southern Russia.

The Increasing Frequency of Cancer.—The number of cancerous cases in England and Wales has increased from 4500 in 1840 to 40,000 in 1895.

Yellow Fever at Port au Prince.—Yellow fever of a malignant character has broken out at Port au Prince, Haiti. It will probably continue to be fatal for some weeks.

Unwholesome Sandwiches.—In Hollidaysburg, Pa., some sixty-five guests were poisoned at a social gathering by

eating ham sandwiches. Severe sickness, but no fatalities are reported.

Deaths from Tight Lacing.—Two London inquests held within a week have resulted in verdicts that death was caused by tight lacing. The autopsy in one case revealed cirrhosis of the liver.

Ohio Boards of Health to Regulate Plumbing.—By a provision of the last Legislature, any person, firm, or corporation engaged in plumbing in Ohio is required to take out a license. Inspectors of plumbing are to be appointed in each city or town.

The Grafe Gold Medal.—The German Ophthalmological Society has awarded the Gräfe medal to Professor Leber of Heidelberg. This honor is conferred every ten years. The first one was received by Von Helmholtz for his discovery of ophthalmoscopy.

A Clinic for Defective Speech.—The Polyclinic Hospital in Philadelphia has established a department for the cure of speech-defects which do not require surgical or special medicinal treatment. The department will take cases that need training in vocalization and articulation.

A Chair of Massage.—The University of Berlin has established a department devoted to massage, over which Dr. Zabloudovsky has been appointed professor. This modern therapeutic method has never before received such distinguished recognition in a great university.

Photographing the Retina.—At a recent meeting of the Paris Academy of Medicine, M. Guinkoff stated that he had photographed the interior of the eye successfully. Actual pictures of retinal disease can thus be secured and compared, from time to time, to determine the progress of the disease.

The Morgue-keeper Suspended.—A. N. White, keeper of the morgue at Bellevue Hospital since 1868, was suspended last week to await an investigation by the Commissioners of Charities. It is charged that there has been an unlawful traffic in dead bodies, and that three in particular are not accounted for.

A Good Stroke.—On November 10th the Illinois State Board of Health announced that the National Medical School, the Illinois Medical College, and the Durham Medical College, all of Chicago, had failed to comply with the requirements of the board, and were therefore excluded from official recognition, and their diplomas refused.

Damages Wanted for Catching Cold.—The Pullman Palace Car Company has been sued in St. John, N. B., for $25,000. The complainant alleges that the heating-apparatus, through the negligence of the company, failed to work, and that he contracted a violent cold while asleep, from which a long illness and permanently impaired health resulted.

Typhoid Antitoxin.—Many experiments have been made with only moderate success in elaborating an antitoxin against typhoid fever, but bacteriologists, with commendable zeal, are pursuing the investigation. Through the Department of State at Washington we are now informed that Professor Pfeipper and Dr. Kolle of Berlin have attained methods which promise to furnish most efficient and prompt results.

Football and Prize-fighting.—Mr. Crisp, a member of the Missouri Legislature, states that during the present winter he will introduce a bill to place the game of football on the same plane as prize-fighting, which, in the State of Missouri, is a felony. The difference between the two sports most apparent to a disinterested observer is that the element of danger in the one is multiplied eleven-fold in the other.

Typhoid Fever in Paterson.—Forty-five cases of typhoid fever have been reported in Paterson, N. J., during the past month as against twelve for the corresponding month of last year. The water-supply of that city is procured from above the Passaic Falls, and is considered exceptionally pure. The local physicians have so far been unable to offer a probable explanation for the infection, but report the cases as uniformly mild.

Lactation and Albuminuria.—Dr. Gamulin finds that the practice of suckling is, as a rule, favorable to the reduction of albuminuria, and to the satisfactory nutrition of both mother and infant. Of 158 albuminuric mothers under supervision, who nursed without interruption, only two showed an increase in the albumin excreted, while in only seven others did the amount remain stationary. Among 163 children nursed by those mothers the mean gain in weight was thirty-five grams per day.

Dr. Jameson's Condition.—Since submitting to an operation, about two weeks ago, the health of Dr. Jameson, of South-African fame, has been such as to excite grave alarm among his friends. On the 28th ultimo, under direction of the government, Sir William Broadbent visited him in the Holloway Jail, London, where he is serving a sentence of fifteen months. As a result of the examination, Sir William advised the speedy release of the prisoner. Even immediate removal may come too late to restore his shattered health.

Successful Use of Antivenene-serum.—A small boy in India was bitten upon the bare foot by a *Bungarus ceruleus*, which, next to the cobra, is considered the most destructive snake in India. Luckily, the boy was seen within three minutes after the accident by Surgeon-Major Rennie, who injected 8 c.cm. of Professor Calmette's antivenene. The effect was all that could have been desired, as the patient recovered without a bad symptom. This is the second or third case successfully treated by the serum, and is important, as the hope that it would prove an antidote against the venom of all varities of reptiles seems thereby confirmed.

Operation for a Ventricular Stab Wound.—At the recent meeting of the Congress of German Scientists and Physicians, Rehn of Frankfort showed a patient who had had a stab wound of the right ventricle. He was admitted

into the hospital moribund from copious hemorrhage. The speaker resected the ribs, exposed the heart, enlarged the opening of the pericardium, and sutured the wound in the ventricle. The operation was rendered more difficult in its later stages by the movement of the heart around its long axis. The hemorrhage ceased immediately after suturing. The operation was done fourteen days before the patient was shown.

An Ambulance-ship.—Surgeon-General Tryon and Secretary Herbert of the navy are both fully convinced of the great utility of adding to our navy one or more suitably constructed ships, whose duty shall be to save and care for all wounded and drowning men during an engagement. It is recommended that this vessel shall be of such size as will render it easy of control in action, and swift and efficient in rescuing the large number of sailors who are swept overboard in almost every naval conflict. Such a ship would receive the same consideration and courtesies accorded the wearers of the Red Cross by all civilized nations. The advantages of such a plan have been so impressed upon the minds of all who entertain a proper regard for the lives of our brave sailors that the equipment and trial of these ambulance-ships may be expected as one of the early improvements in the United States Navy.

CORRESPONDENCE.

SECOND PAN-AMERICAN MEDICAL CONGRESS.

Held in the City of Mexico, November 16, 17, 18, and 19, 1896.

[From our Special Correspondent.]

HOTEL DEL JARDIN,
CITY OF MEXICO,
November 20, 1896.

CONTINUING my account of the first day's session, Dr. Rafael Lavista of the City of Mexico followed with a paper on the subject of the toxin and antitoxin treatment of disease by subcutaneous injection of serum. He referred to the experiments made by himself and other Mexican investigators in the treatment of tuberculosis, leprosy, and cancer, and said that their results had not been encouraging. Patients suffering from syphilis had received temporary benefit from the treatment, but a cure had not been obtained in a single case. No satisfactory results had been obtained from the serum treatment of typhus, septicemia, or tetanus. He had had no experience with diphtheria nor typhoid fever, as both of these diseases were of rare occurrence in Mexico. The Mexican profession had very generally followed the practice of injecting large quantities of normal salt-solution as a preventative of surgical shock, and after hemorrhage, and always with marked beneficial results. Personally, he favored the intravenous method.

Dr. Ricardo Lee of the United States of Colombia then read a most interesting paper on "The Prophylaxis of Leprosy." He dwelt at length on the rapid increase of the disease in southern countries, and said that in Colombia it was giving rise to grave concern. He urged the adoption by the State of certain hygienic and social laws that would tend to prevent the spread of the plague, and laid stress upon the importance of encouraging immigration from other countries, whereby new blood would be introduced and the social status of the inhabitants improved.

The Third General Session of the Congress was held on Thursday evening, November 19th, and with its close, Minister Baranda officially declared the Second Pan-American Medical Congress at an end.

Dr. Porfirio Parra read an address, in which he referred to the recent advance in all branches of medicine during the past ten years, and he was followed by Dr. Charles A. L. Reed, who announced that the executive committee had decided that the next Congress would be held in December, 1899, at Caracas.

The official delegates from Canada, Cuba, Colombia, Guatemala, Nicaragua, Ecuador, Venezuela, and Costa Rica were then introduced, and each delivered an address.

The work done in the different Sections of the Congress was exceedingly interesting and valuable. In that devoted to General Medicine, on Monday, Dr. William Pepper read a paper on "The Use of the Röntgen Ray in Thoracic Aneurism," and exhibited a number of excellent skiagraphs in which the aortic enlargements were distinctly visible. He said that the taking of the skiagraph was probably made possible in these instances from the fact that the rays were arrested by the large amount of blood contained in the tumor, and were also influenced by its iron constituents. He had distinctly seen the pulsation of a human heart by the aid of a specially designed tube, and the anatomical parts of the organ were clearly to be made out. This great discovery of the X-ray was still in its infancy, as far as its application was concerned, and he had every reason to suppose that the next year or two would see remarkable advances in this direction.

Dr. Manuel Ruiz Casabó of Havana read a paper on "The Urine in Yellow Fever." This disease was so prevalent in his native city that his opportunities for studying and comparing the characteristics of the urine in it and other diseases had been of an exceptional kind. He said that the appearance of the urine in cases of yellow fever was very variable, according to the individual attacked, but that there were certain characteristic peculiarities that were nearly always present. He read a number of interesting tables of statistics, the result of his investigations.

He was followed by Dr. E. Acosta of Havana, who read a paper on the same subject, prepared by himself and Dr. J. M. Dávalos. It referred to the establishment in Havana, in 1887, of a bacteriological laboratory for the study of infectious diseases. Yellow fever had been exhaustively studied by the authors, and a large number of experiments on rabbits had been made. The conclusions arrived at were that the greater part of the toxin of the disease was eliminated in the urine, and that an examination of the fluid conclusively demonstrates the severity of the attack; that the amount of urea present in the urine bears no relation to the prognosis, and that the patient never dies from uremia, but from the constitutional effect of the toxin.

Dr. Tomás Vincente Coronado of Havana then read a paper on "The Biological Characteristics of the Blood in Yellow Fever," the sum and substance of his investigations being that in this disease the blood showed absolutely no change from the normal state. Blood taken with careful antiseptic precautions, a few hours before death, from a patient suffering from the disease, was precisely similar to that from a perfectly healthy individual. This fact conclusively proved that the seat of the disease was not in the blood.

"Cantharidal Blisters in Acute Pulmonary Affections" was the title of a paper read by Dr. José de la Cerna of Calimaya, Mexico. The author does not approve of the blisters in this connection, as their use will increase the local congestion, and is apt to decrease the amount of urine secreted. As the kidneys are always congested in acute pulmonary affections, one of the principal indications, that of free diuresis, is interfered with to a marked degree.

Dr. J. Llambías of Buenos Ayres read a paper on "The Spontaneous Rupture of the Aorta," in which he claimed that a satisfactory explanation of this accident had not yet been arrived at. He was inclined to think that it is primarily due to an interruption of the blood-current in the vasa vasorum, which ultimately leads to an endarteritis of these vessels, a necrosis resulting from this condition.

At the meeting of the same Section on Tuesday, the second day of the Congress, Dr. Ignacio Ortiz y Córdoba of Cuernavaca, Mexico, presented a case of perineoscrotal hypospadias in an individual, Maria Hernandez, by name, in whom the imperfect act of coition was performed as a male, but in whom the habits, dress, and character were those of a woman.

Dr. A. Holmes of Denver, Col., read a paper on "The Diagnosis of Tuberculosis by Means of a Microscopical Study of the Blood," and was followed by Dr. J. K. Crook of New York in a paper entitled "The Use of Creosote in the Treatment of Pulmonary Diseases." Dr. Holmes referred at length to all that has been accomplished of late in the microchemical study of the blood in tuberculosis, and claimed that in the position in which the science of medicine now stands it was possible not only to recognize the presence of the disease in its incipiency, but that certain marked changes may be made out in the blood of an individual who is of a tuberculous predisposition. He urged that investigations along this line be continued, and that the microscope be brought into requisition at every opportunity, as an early diagnosis of the disease would enable one to take advantage of approved therapeutic and climatic measures.

In the Section on Obstetrics and Gynecology Dr. A. Vanderveer of Albany, N. Y., presented a paper on the subject of "Uterine Fibroids Complicated With Pregnancy." He said that these cases are by no means common, and that unless the position of the tumor is such as will probably interfere with the labor, it is always advisable to delay any operation devised for its removal.

Dr. J. Ignacio Capetillo of the city of Mexico then read a paper on "Dystocia in Mexico," in which he said that on account of the comparative rarity of contracted pelves in Mexican women maternal dystocia is not of frequent occurrence. Prolapsus of the cord and placenta previa are most often met with.

"The Management and Surgical Treatment of Ectopic Pregnancy" was the title of a paper read by Dr. A. P. Clarke of Cambridge, Mass. He expressed the opinion that the galvanic or faradic current could be used to advantage in destroying the fetus, if used very early. In later cases one should always be prepared to do an abdominal section, as hemorrhage or sepsis is apt to be rapidly fatal to the mother if the case is not given immediate attention. Tubal pregnancies are the ones that usually give rise to most marked symptoms.

Dr. Emma B. Culbertson of Boston, Mass., presented the next paper on "The Ambulant Treatment of Certain Forms of Pelvic Disease." She said that many of the patients who apply for gynecological treatment are so circumstanced that the routine of their daily work must not be interfered with, and that, in consequence, the treatment must be so arranged as to be most efficient under these conditions. Malposition, inflamed and congested ovaries and tubes, endometritis, and venereal disease, are the usual affections of this class of patients, and should receive prompt and careful treatment.

"The Treatment of Face Presentations" was the title of a paper read by Dr. José Torres Anzorena, and "The Therapeutic Value of Rest," by Dr. Sarah H. Stevenson. Dr. Antonio Macías read an interesting paper on "The Use of Potassium Iodid in Passive Metrorrhagia," and Dr. E. J. Ill of Newark, N. J., closed the list with one on "A Contribution to the Surgery of the Female Perineum."

On Tuesday, at the second meeting of the Obstetrical and Gynecological Section, the proceedings were opened by the reading of a paper by Dr. J. Ignacio Capetillo of the city of Mexico, describing a case of hydatidiform mole, which had given rise to alarming uterine hemorrhage, and which had been diagnosed as placenta previa.

Dr. Manuel Barreiro, also of the City of Mexico, followed with a paper on "Puerperal Septicemia." He described the routine practice in all cases of confinement at the Maternity Hospital of the city of Mexico. The day following delivery a laxative, and a tepid antiseptic vaginal douche, is given, and the latter repeated every day during the entire puerperium. If the temperature of the patient arises, an intra-uterine douche is given, but if this is ineffectual, a curettage is resorted to at once. The curette may be used a second, and even a third time. The patient is carefully stimulated, especially with strychnia.

Dr. Gonzales de la Vega continued this subject, the title of his paper being "Observations on the Classical Treatment of Puerperal Septicemia," and other papers were read by Dr. Henry Schwartz of St. Louis, Mo., and Dr. Rafael Norma of Tulancingo, Mexico.

The Section on General and Orthopedic Surgery was called to order on Monday, and Dr. Angel Contreras of Puebla, Mexico, opened the proceedings by reporting the case of a boy, six years of age, suffering from tuberculosis of the knee-joint, who was cured by Albertin's method of arthrectomy.

Dr. George W. Crile of Cleveland, O., presented a paper on "Researches into the Technic of Laryngeal Operations, with a Report of Four Successful Total Extirpations," and was followed by Dr. A. D. Spohn of Corpus Christi, Tex., who exhibited a new device to be used in the treatment of fractures of the clavicle.

Dr. E. B. Smith of Detroit, Mich., read the closing paper, which was on "Gastro-enterotomy."

At the Tuesday meeting, Dr. J. A. Fort of Montevideo, Uruguay, read a paper on "Linear Electrolysis in Stricture of the Urethra," in which he described at length the method of procedure devised by him several years ago.

An interesting operation of intestinal resection and anastomosis was performed later on a large dog, at one of the hospitals, by Dr. J. Frank of Chicago, who demonstrated his method of procedure with bone buttons held together by a section of rubber drainage-tube.

Taken altogether, the second Pan-American Medical Congress has been an unqualified success. The papers presented, and the discussions, have been of a thoroughly scientific character, and much good is bound to result from the interchange of opinion between members of the profession living so widely apart. These results will undoubtedly be in evidence before the date of the next meeting. The hospitality and courtesy of those who have entertained us could not have been exceeded, and every visitor will carry away with him the happiest recollections of his stay.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting November 27, 1896.

JOSEPH D. BRYANT, M.D., President.
(In charge of the Section on Obstetrics.)

J. CLIFTON EDGAR, M.D., read a paper on

THE TREATMENT OF ECLAMPSIA.

He said that about all that we knew, even at the present day, regarding the nature of puerperal eclampsia, was that it was a form of toxemia. Modern clinical research had, however, brought out the fact that the "pre-eclamptic state" often extended over a period of weeks or months, and manifested itself by easily recognized symptoms and signs. While Dr. E. P. Davis of Philadelphia had shown that where these toxic symptoms were present the urea would be found below 1.5 per cent., and that these symptoms were improved, or made to disappear, by stimulating the excretory organs to activity, it must not be forgotten that there are other toxic substances in the urine besides urea, and that eclampsia sometimes occurs even when the urea is excreted in normal quantity. While the etiology of the toxemia producing puerperal eclampsia was obscure and probably complex, clinical observation points strongly to the metabolism of the fetus as a prominent cause of this toxemia. The successful treatment of puerperal eclampsia must therefore depend upon a prompt recognition of the pre-eclamptic state. This was not to be accomplished by an occasional examination of the urine for albumen alone, as non-albuminuric eclampsia forms from nine to sixteen per cent. of the cases. Other sources of toxemia must be given due consideration. The treatment might be conveniently divided into three parts, *viz.:* (1) The reduction of the amount of nitrogenous food to a minimum; (2) the limitation of the formation and absorption of toxic materials in the intestine and tissues of the body, and the stimulation of the emunctories; and (3) the removal, if necessary, of the source of fetal metabolism by emptying the uterus. The first indication was met by an exclusive milk diet for a time; the second, by securing an abundant supply of pure air and water, and the taking of moderate exercise, together with a proper regulation of the bowels; the third, by the induction of abortion or premature labor, if the symptoms were urgent and did not abate under a milk diet and stimulation of the excretory organs. In cases of eliminative insufficiency, he had found it useful to administer about twice a week, at bedtime, a tablet containing 1 grain each of calomel, digitalis, and squills, and $\frac{1}{10}$ grain of muriate of pilocarpin. Care should be taken to protect the body-surface by good, warm clothing. It could not be too strongly insisted that the foundation of the preventive treatment of puerperal eclampsia was an exclusive milk diet. Regarding the induction of labor, it should be remembered that many obstetricians of repute objected to it on the ground that it produced a dangerous increase of the already abnormal reflex excitability, and was therefore liable to precipitate an attack of puerperal eclampsia. Certainly, this argument carried with it much weight, but, on the other hand, it could not be denied that at the present time it was possible to induce labor very quickly, without undue excitement, and at the same time terminate the pregnancy.

The curative treatment of puerperal eclampsia must be to a certain extent empirical so long as our knowledge of the pathology of this condition is so meager. There are three general indications, *viz.:* (1) The control of the convulsions; (2) emptying the uterus under deep anesthesia by some rapid method, and (3) elimination of the poisons which are presumably responsible for the convulsions. Of the drugs used for controlling the convulsions, he personally favored chloroform, veratrum viride, and chloral, in the order named. He used morphia much less frequently than formerly in these cases, because he had become convinced that it tended to prolong the post-eclamptic stupor, and to increase the tendency to death during coma by interfering with the eliminative processes. The power of veratrum viride to reduce the pulse-rate and the temperature, and at the same time to relax the cervix and produce diaphoresis and diuresis, made it an especially valuable remedy. As the danger from eclampsia was over in ninety per cent. of the cases as soon as the uterus had been emptied, the importance of early and rapid delivery was obvious. For this purpose, he believed the rapid manual dilatation of the os and the subsequent extraction of the child constituted the best method, but it should be remembered that unless complete dilatation of the internal os and paralysis of the cervix were obtained, there was great danger of rupturing the uterus, as well as of sacrificing the child by the closure of the cervix around the

armpits of the fetus during extraction. In cases in which immediate delivery was urgently demanded, and the internal ring of the os had been drawn up into the body of the uterus, and the external ring remained rigid, he would prefer to make four clean incisions extending from the edge of the os to the utero-vaginal junction. In addition, the bowels should be freely moved by croton-oil or calomel, followed by a saline, and by high enemata of a solution of magnesium sulphate. Diuresis should be excited by the application of cups and fomentations over the kidneys, and by the internal administration of glonoin or veratrum viride. Diaphoresis was best promoted by means of a hot-air bath. In this stage, pilocarpin was a most dangerous drug, tending to cause fatal pulmonary edema.

Much misapprehension has been caused, the speaker said, by the use of the term *accouchement forcé*. In its modern acceptation it was applied to the complete instrumental or manual dilatation of the cervical canal, followed by version or forceps, and the immediate extraction of the child. It does not mean the dragging of a fetus through a partially dilated os. As puerperal eclampsia was so much more common in primiparæ than in multiparæ, it often became necessary to resort to some method of preliminary dilatation of a rigid os before the more radical procedure could be attempted. This necessarily caused some delay, and during this time it would be found that the administration of veratrum viride would save many lives.

DR. E. P. DAVIS of Philadelphia said that he was becoming more and more convinced that the only really successful treatment of puerperal eclampsia was preventive —in other words the treatment of the preëclamptic state. The physician, in examining the urine of pregnant women, should determine the percentage of urinary solids as well as the albumen. Not infrequently the nervous symptoms —the mental depression, irritability, or headache—gave us the first hint of the impending danger. Here it would be found that a warm bath at night would not only give the needed rest, but would promote elimination. In the preëclamptic state there could be no doubt that it was the imperative duty of the physician to terminate the pregnancy if the eliminative treatment proved ineffectual. For the complete dilatation of the cervix he had found nothing better than the Barnes' bag. The control of the convulsion by chloroform was, of course, indicated. The emptying of the uterus by Cæsarean section would seem to be the ideal surgical method, but it should be remembered in considering the value of the child's life, and weighing its chances with those of the mother, that these children often lose their lives after birth from the same toxemia that has affected the mother. He had found atropin very useful at times for the control, not only of the convulsions, but also of the pulmonary edema.

DR. CHARLES JEWETT of Brooklyn said that he agreed with all that the last speaker had said about the significance of the nervous symptoms; nevertheless, he thought that in many instances these symptoms would not be brought to the notice of the medical attendant, and that, therefore, the attention of the latter should in all cases be largely concentrated on the condition of the urine as indicated not alone by the presence of albumen, but by the percentage of solids excreted. Where ordinary remedial and dietetic treatment failed to remove these symptoms and signs, the induction of labor was certainly justifiable. His inclination was to interfere too soon, rather than too late. He did not believe that in practice the period of viability could be placed much earlier than the ninth month. Chloroform was exceedingly useful in controlling the convulsions, but was dangerous if long continued. In addition to the rapid emptying of the uterus, he had depended mainly upon catharsis and diuresis, and the administration of veratrum viride. The latter he believed to be the most valuable of all the drugs used in puerperal eclampsia. Venesection was most useful, and, in his opinion, would gain more general recognition in the future. He had also found the injection of saline solution into the tissues and into the bowel an excellent means of favoring elimination. In the preventive, as well as in the curative treatment, he was in the habit of depending largely upon the free administration of water. He had found that an exclusive milk diet could not well be continued for more than two weeks at a time.

DR. EGBERT H. GRANDIN agreed heartily with Dr. Davis that puerperal eclampsia is a *preventable* disease; that is to say, if a pregnant woman has been for some time under the observation of her physician, she should not have eclampsia. We had been taught to watch too much for albuminuria, and too little for uremia. In a case of impending eclampsia, the rule should be rapidly to dilate the cervix with the hand and deliver. Any time after seven and one-half months of uterogestation, the hand alone could empty the uterus in less time than any drug could act, and the woman be thus placed out of danger. The procedure described and advocated by Dr. Edgar was not an *accouchement forcé*, for there was nothing forcible about it; it was simply the yielding of a muscle under pressure, just as in the familiar case of the dilatation of the sphincter ani. When time permitted, it was, of course, better to use a preliminary gauze-tamponade for six or eight hours, but where the symptoms were too urgent for this after seven and one-half months of uterogestation, rapid manual dilatation was the proper procedure. In his opinion, any one who, under these circumstances, could not dilate the cervix and empty the uterus within thirty minutes, in ninety-eight per cent. of the cases, did not know how to do it. Care should be taken to paralyze completely the lower uterine segment before attempting extraction. He always preferred chloroform, and gave it to the surgical degree. The dilatation should be performed finger by finger, until the whole fist could be introduced and the hand could be opened and shut. To secure proper elimination of the poison after delivery, he advised washing out the colon with sixteen or twenty gallons of hot salt water. He did not think Cæsarean section was called for when the lower uterine segment could be entered. He had only found it necessary to resort to deep cervical incisions in one case.

DR. W. T. LUSK said he regretted that there was at present a tendency among some modern obstetricians to

terminate pregnancy without what appeared to him sufficient reason. Calling a method the "surgical evacuation of the uterus" did not alter the fact that an abortion was performed. The existence of an insignificant quantity of albumen in the urine called rather for dietetic treatment than for radical surgical interference. If the daily quantity of urine were much below the normal daily average, in the absence of other urgent signs and symptoms, the indication was to put the patient on an exclusive diet of milk. In his opinion, the artificial evacuation of the pregnant uterus was not so simple and insignificant matter as many claimed. As every convulsion adds to the dangers of the mother, any method which would save her from even one or two convulsions was of benefit. He believed that he could secure nearly as rapid results from the Barnes' dilator as from almost any other method. It had been found that Duhrssen's deep cervical incisions were liable to be followed by serious hemorrhage.

DR. JAMES W. MCLANE said that the cases of puerperal eclampsia coming under his observation could be divided into two grades, *viz.:* (1) The more common variety in which there was a mild toxemia, associated with slight albuminuria, and but few nervous symptoms; and (2) a much more severe form—a sort of toxemic explosion of complex origin. The patients coming under the first variety he rarely treated medicinally, preferring to keep them on a milk diet, insisting on rest in bed for a part of each day, and the taking of a daily bath, with very moderate exercise. From what he had seen of the second class he could not agree with those who said that puerperal eclampsia is an entirely preventable disease. He had known of several cases in which notwithstanding frequent and careful examinations of the urine, an attack of eclampsia had occurred. If seen prior to the attack, when the pulse was full and bounding, and the patient complained of severe headache and dimness of vision, nothing could yield better results than a venesection of perhaps sixteen ounces of blood. He did not at all agree with those who believed that the child was damaged by the mother's condition, and, in support of this view, cited a case in which after twenty-seven convulsions the mother had given birth to a vigorous child. He had found that prompt rupture of the membranes often acted nearly as well as venesection in controlling convulsions. He had seen cases in which it had been utterly impossible for the strongest hand to dilate the cervix in thirty minutes except the uterus were ruptured. He would prefer a gentler method because of the probable disastrous effect on the impressionable nervous system of the eclamptic woman. After delivery he favored giving small quantities of chloroform by inhalation for some time, the patient being kept in a hot pack, then substituting morphia for the chloroform. He had not used veratrum viride because in most cases he had found the pulse small and feeble after two or three eclamptic attacks. A steady and excessive rise of the body-temperature was a very bad prognostic sign in puerperal eclampsia. As he had known pilocarpin to produce fatal edema of the lung in cases of puerperal eclampsia, he regarded its administration in this condition with horror.

DR. ROBERT A. MURRAY said that he had often been well pleased with the beneficial action of early rupture of the membranes in these cases. However, venesection should be considered the sheet-anchor of the obstetrician in dealing with these cases. A busy physician might easily neglect to examine the urine of the pregnant woman for urea, but he had no excuse for omitting to take the specific gravity, and so determining the quantity of urinary solids being excreted. He could corroborate everything that Dr. Grandin has said about the rapid manual emptying of the uterus, and its success, even in primiparæ. He did not see how any one could rupture the uterus during dilatation, although it might easily occur during the process of extraction. The process of manual dilatation could be substantially aided by venesection and the use of chloroform, and when the operator's hand became tired it could be withdrawn for a few minutes, and the uterus allowed to relax. One great advantage of the manual method was that it enabled the obstetrician to determine quickly the relative size of the fetus and the maternal pelvis, and so guided the operator in the choice of the method of delivery. A large proportion of the children born of mothers suffering from eclampsia died of uremia after birth, even when delivered normally.

DR. PHILANDER A. HARRIS of Paterson said that he had employed, with much satisfaction, a method of manual dilatation which he had devised, and the results certainly supported the position taken by Dr. Grandin.

DR. BERNARD E. GORDON said that he had also found that rapid delivery could be effected by the hand.

DR. EDGAR, in closing the discussion, said that he was grateful to Dr. Davis for referring to the train of nervous phenomena as symptoms of the preëclamptic condition, as these had been omitted from his paper. He had come to rely so much upon the physical signs that the nervous symptoms seemed of minor importance. Still, it must be admitted that in some instances these very nervous symptoms are the earliest clinical index of an approaching eclamptic seizure.

He had only found the hydrostatic bags of Barnes useful as preliminary measures, *i.e.*, to prepare the cervical ring for a more rapid and thorough subsequent dilatation. Cæsarean section as a means of rapid delivery in an eclamptic attack he would absolutely reject. Charpentier had shown, as had been pointed out in the paper, that the operation still carried with it a maternal mortality of 36.26 per cent. in eclampsia. Moreover, in the absence of pathological conditions of the cervix, he believed there was no cervix that could not be dilated, either by manual dilatation or incision, in sufficient time to meet every indication. He was in accord with Dr. Davis as to the value of atropia hypodermatically, not only for the edema of the posteclamptic state, but also for its antieclamptic action. The point which he wished to make the most prominent in the paper was that the only successful preventive treatment of puerperal eclampsia rested on the early recognition of the preëclamptic state, as shown in the early diagnosis of eliminative insufficiency.

He was quite in accord with Dr. Jewett's proposition, that it was far better for the patient suffering from eliminative insufficiency to have labor induced too early rather

than too late. Dr. Jewett was the only one who had referred to the stupefying action of chloroform. This he had only touched upon in the paper, and believed it should be given greater prominence. He was satisfied that the less anesthetics and narcotics the patient received the better. Not only chloroform, but morphin, chloral, and the bromids deepen the posteclamptic stupor and coma, and increase the tendency to death during the coma by reason of these drugs interfering with the eliminative processes. In certain maternities, chloroform had been abandoned, except where operative interference was demanded. He relied, as far as possible, upon veratrum viride, which not only controls the convulsive seizure, but promotes diaphoresis and diuresis. He considered the statement that after seven and a half months all cervices would yield, and allow of manual delivery within thirty minutes, dangerous teaching. It was just such statements that had led to the accidents referred to in the paper. Further clinical experience, he was sure, would cause the speaker to modify this statement. He agreed with Dr. Lusk that the daily amount of urea excreted was only one physical sign; but when considered in conjunction with other signs and symptoms, one could properly decide whether such operative interference as the induction of labor was demanded. The use of the Barnes' bag was an excellent preliminary measure, but to secure full dilatation, so that the fetus could be extracted with safety to both itself and mother, it was not to be compared, in his opinion, to the careful bimanual stretching and paralyzing of the cervical rings. Dr. Murray's statement that it was impossible to rupture the uterus during the performance of a manual dilatation was answered by the instances of partial and complete rupture of the uterus referred to in his paper. He was familiar with Dr. Harris' method of digital and one-handed dilatation of the os, and had given it a trial in hospital practice. Personally, he had found the bimanual method the most satisfactory, particularly for the reason that he could produce complete paralysis of the external ring of the os. This he could not do with Dr. Harris' method. He could not subscribe to Dr. McLane's practice of early rupture of the membranes as an efficient antieclamptic measure. It was true that the rupture of the membranes at this time apparently controlled the convulsions temporarily, but his experience had been that subsequently the presence of the fetus in the uterus, not surrounded by its cushion of liquor amnii, was a greater source of peripheral irritation than when the membranes were intact and the liquor amnii present. The worst instances of eclampsia seen in the emergency-cases of the maternity hospitals were those in which the membranes had ruptured early spontaneously, or had been artificially ruptured in the first stage. Moreover, the subsequent labor was prolonged, and the difficulties and dangers of operative interference enhanced by such a procedure.

It had been the experience of most observers that the high arterial tension does not always diminish or disappear after one or two eclamptic seizures. He had seen many cases in which the high tension had persisted for days, and even several weeks, and in which the continued use of glonoin and veratrum viride had been necessary to combat this symptom and prevent subsequent eclamptic attacks. While he objected strongly to the use of pilocarpin in the presence of an eclamptic attack, he believed it would be found a valuable adjunct in the treatment of the eliminative insufficiency of pregnancy—the preventive treatment of eclampsia.

That those eclamptic women do best in whom a rapid dilatation of the cervix and evacuation of the uterus is not performed, is the teaching of Charpentier of Paris; but, as the reports of the last Congress show, he stands almost alone in the world in this position. The speaker said that the greater his clinical experience with puerperal eclampsia, the more convinced he was of the truth of Duhrssen's statement that in ninety per cent. of eclamptic cases the danger was practically over when the uterus had been rapidly emptied early in the attack. He was firmly convinced that a careful study of the anatomy and physiology of the pregnant and parturient cervix would satisfy any unprejudiced observer, that the operation could not only be performed without any additional danger to mother or child, but that it was a life-saving procedure for both parties concerned.

Violation of the Postal Laws.—A Cincinnati physician was recently fined $100 and costs for sending a dunning postal card to a delinquent patient.

Honored by the Chinese Emperor.—Surgeon-Major Hueston of the British army, professor in the medical school at Tientsin, has been made a mandarin. He has also received the decoration of the Order of the Double Dragon from the Emperor of China.

Tuberculosis in French Colleges.—The Minister of Public Instruction in France, in a letter to the rectors of universities, directs that tuberculosis shall be added to the list of contagious diseases. He says that the interests of the patients themselves imperatively demand that they should not be under college discipline.

The Yucca-palm in Surgery.—In Los Angeles, Cal., a manufacturing plant is devoted to making splints and various similar surgical appliances from the wood of the yucca-palm obtained from the Mojave desert. When seasoned, the fiber is so tough, light, and hard that it has no rival for the above-mentioned purposes.

Effect of Antipyrin on the Kidneys.—Cardi and Tallini, from a series of experiments on animals, conclude that antipyrin has a direct constrictive effect upon the renal blood-vessels, and increases the general blood-pressure slightly and transiently. This is accompanied by a diminution in the renal secretions, which persists for some time.

Ozone and Tuberculosis.—Out of thirty-eight cases treated with ozone, Labbi and Indén report seven cured in the first degree, six in the second, sixteen markedly improved, and six died. There was a notable increase in the oxyhemoglobin, and in the numbers of the red blood-corpuscles. The inhalations were only given for fifteen minutes daily.

THE TREATMENT OF APPENDICITIS.[1]

BY CHARLES McBURNEY, M.D.,
OF NEW YORK;
VISITING SURGEON TO ROOSEVELT HOSPITAL, PROFESSOR OF CLINICAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

I INTEND to give you an informal talk to-night, dwelling especially upon certain questions of treatment of appendicitis. It is a singular fact that inflammation of the appendix vermiformis as a separate disease had not been identified nor described by pathologists previous to 1886. In that year a paper upon pericecitis appeared by Dr. Reginald H. Fitz of Boston. This gave the true pathology of a disease which is now so well known. In the development of our present knowledge of the pathology and treatment of appendicitis there have been three well-marked stages. The first stage began when Willard Parker first practised opening the so-called perityphlitic abscesses. This was in 1866 or 1867. Dr. Henry B. Sands was at that time Dr. Parker's partner, and I was a student in Dr. Parker's office. Dr. Parker deserved great credit for his boldness and originality. At first he opened only large, dull, and clearly defined abscesses, letting the smaller and less plainly marked ones go. After Dr. Parker's retirement from active practice, Dr. Sands carried on the work which the former had so well begun. As said above, however, the true pathology of the condition was not known until the appearance of Dr. Fitz' paper in 1886, which explained the lesion so accurately that no material addition has since been made to the pathogenesis of the disease. The proper surgical treatment was not determined for some time after this. This period of the development of the treatment was the second stage. Dr. Sands was constantly working at this surgical problem, and to him is due the whole credit for bringing the operation to a state of perfection. Thus the third stage of the development of the surgical treatment of appendicitis was reached. Dr. Sands first successfully removed the diseased appendix from a young boy, a patient of Dr. Simon Baruch. It is a matter of surprise that the name of this operator is so seldom met with in the literature of the subject at the present day. Certainly one would expect that he would receive more general acknowledgment for this brilliant surgical achievement.

The obstinate resistance which Dr. Sands' operation called forth in many quarters seems laughable as we look at it now. In that day nearly every one agreed that the disease, in common with general peritonitis, should be treated with opium. Even progressive surgeons shivered at the thought of an operation which proposed to invade the abdominal cavity so freely. Only six years ago a surgeon of large experience decided against operation in a case of appendicitis because, as he alleged, all of his cases had recovered without operation. Another surgeon, in a paper published five years ago, claimed that twenty other diseases might be confounded with appendicitis. It was alleged in a paper that appeared in a recent number of a prominent medical journal that the cause of the disease is rheumatism, and the treatment should therefore be antirheumatic. Such suggestions may be, and no doubt have been, productive of much harm by inducing practitioners to dally with cases of appendicitis expecting the administration of salicylates, salol, etc., to do good. Is there any purely medical measure which may be relied on to cure this disease? I know of none. Perhaps it is as well that we should know that there is no remedy of a medical nature, because while we are searching for some drug to cure the patient we may be doing him irreparable damage by delay. Appendicitis must logically, I think, be placed among the surgical diseases. This does not mean of course that every case must be operated upon, nor, on the other hand, does it follow that because certain cases recover without surgical interference the complaint is to be taken out of the list of surgical diseases. I would not be understood as saying that many purely medical men are not as clever as any surgeon in making the diagnosis of appendicitis, and as anxious to have the case treated on the best surgical principles. There are two classes of medical men who take different views of the treatment of the disease: one I have just mentioned; the other looks upon all cases as really medical in character, seldom requiring any surgical measures for their relief. These practitioners approach the subject from totally different standpoints and too often prejudge a case without studying the conditions with sufficient care. The disease is therefore not so well studied or handled as it might be. This state of things is, however, gradually being cleared

[1] Read before the Orange Mountain Medical Society.

up, and in time the disease will surely be placed in its proper category.

As illustrating the evils of an improperly handled case, I might cite one which has recently occurred to me, and which was one of the worst cases I have seen. A young lady of good family, under the care of a medical man, who, I am glad to say, was not a regular practitioner, was suffering from her ninth attack of appendicitis, which she and her family were assured was enterocolitis. The patient herself recognized the nature of her ailment, and demanded an operation. I was called in after the patient had been ill eight days, and while recognizing the extreme gravity of the situation yielded to the solicitations of the patient and her friends to give her the only chance which, in my judgment, remained, *viz.*, an operation. The first incision gave vent to a quart of pus, which spurted to the height of a foot. This was an aggravated case of septic peritonitis due to appendicitis, and naturally terminated fatally.

We are very far from possessing any exact knowledge as to the primary cause of appendicitis. My whole thought has run toward a stoppage of the drainage from the appendix into the colon as the true cause of the disease. There may be an interference with the emptying of the contents of this little tube, due to several lesions; as, for instance, a concretion in the appendix itself, or a stricture, or accumulations of fat causing displacements, or there may be a kink or twist, either in the appendix itself, or in a fold of the colon. I have never seen a case in which there was no interference with the drainage, and I am inclined to the opinion that this cause may account for all the cases. If the appendix be examined *in situ* before its relations have been disturbed, in quite a number of cases the obstruction will be discovered; in others, on the other hand, the cause of the interference with the drainage may have been swept away. If we have a patient not susceptible to sepsis, there may have been only temporary obstruction of the appendix, and only slight constitutional symptoms; while in another, with a similar obstruction, there may have been marked sepsis and great depression from the first, and the case may become rapidly fatal unless relieved by operation. In most cases of stricture no benefit can be expected from preliminary measures of treatment.

I think that the preliminary treatment is often worse than useless, and that the measures adopted in the very beginning are of extreme importance as regards the prognosis. A common procedure is the administration of a large dose of morphine, which quiets the pain and relieves the distress of the patient, but masks all symptoms. This prevents the proper study of the early stage of the complaint, the stage which is the most important both as regards diagnosis and treatment. The question of the rapid or gradual increase in severity and the advent of sepsis are obscured by the opium-treatment. A patient presenting himself with severe abdominal pain, whether he has fever, nausea, vomiting, prostration, and constipation, or not, should be *suspected* of having appendicitis. The most probable cause of sudden, severe, and not otherwise easily explained intra-abdominal pain, is appendicitis. Such a patient should be put to bed and thoroughly examined; very little opium or other anodyne should be given, but the patient must be kept at rest and most carefully watched. If the diagnosis can be made during the first six hours, and the patient can be kept under observation for six hours longer, the progress of the disease may tell the whole story. Certainly, in twenty-four hours from the beginning of the attack, we may be able to decide not only as to the diagnosis, but as to the probable course and result of the case. In my opinion, many of the casualties in this disease are due to neglect of the precautions which I have just recommended. The earlier the choice can be made between operative and palliative procedures the better for the patient.

The question of the proper time to operate in an acute attack of appendicitis would call for a week's discussion, and cannot be answered dogmatically for every case. Indeed, no two cases are alike, and each must be treated according to the indications. Certain well-marked symptoms must be watched for and their value carefully determined in each instance. Let us suppose an average case. The patient has had one or two attacks of vomiting; the pulse is only moderately accelerated, and is of good volume and strength; the temperature is about 100° F.; there is abdominal pain, perhaps quite severe, at first diffused, then settling into one point about half-way between the anterior-superior spine of the ilium on the right side and the umbilicus. If in five or six hours there is no increase in urgency, the patient is not in immediate danger; if in twelve hours there is still no increase in the severity of the symptoms, the patient should soon begin to improve. On the other hand, if the urgency of the case has steadily increased in twelve hours from the time when we were able to make the diagnosis, an operation will probably be called for. If I can safely allow a patient to get over an acute attack before operating, I always prefer to do so. If in twenty-four hours from the beginning of the attack the symptoms lessen in severity, I usually feel sure that I can leave the case to nature for the time being, and defer my operation to a more favorable period. Such an attack ought to subside in from forty-eight to seventy-two

hours. If, however, during the second twenty-four hours of the attack I am doubtful of the outcome, I always advise an operation. This is of course only an imperfect answer to the question, when to operate.

In a given case, one practitioner gets his idea of the course of the attack in one way, and another in another; one relies more upon the facies, another upon the pulse, and a third upon the patient's strength. Here of course experience is of the greatest value. Just as soon, however, as the conclusion is reached that the disease is progressing, the time has come to operate.

I have been asked if I operate on all cases of appendicitis in which the symptoms have practically disappeared, and I have replied that my feelings have changed so much of late that I feel quite willing to do so. Treves lays down the rule that when attacks have been very numerous, and when they have been increasingly severe and threaten life, operation should be done. My own view is that after two attacks a patient will as surely have the third as that after ten attacks he will have the eleventh. There is no rule which applies to the severity of the succeeding attacks. We know, however, that each attack renders an operation more and more difficult, and that it requires a larger incision and involves greater injury to the abdominal wall.

As to the success of the operation itself, all the advantages lie with the operation that is done between the acute exacerbations of the disease. In such an operation we may look for a convalescence of from two to three weeks, unaccompanied by danger from sepsis, or the occurrence of a ventral hernia, and the mortality is almost nothing. In an operation during an acute attack, on the other hand, the prognosis is more grave. The period of convalescence will probably last for about six weeks, and there is decided danger of sepsis and of a subsequent hernia.

The decision of this question, namely, whether or not we can safely allow an attack to go on, and defer the operation, calls for the best possible judgment and experience. In operating between the attacks there is, moreover, a safe time and a bad time. No matter how favorable the patient's condition may seem to be, it is rarely safe to undertake an operation in less than two weeks after an acute attack, for the reason that although the subjective symptoms may be favorable, the local septic condition may not have been entirely removed. After the lapse of two weeks or more all congestion, inflammatory thickening, and danger of sepsis will have disappeared.

I always use a gauze-drain except in cases of general septic peritonitis; then, in addition to abundant gauze-drainage, I use a long glass tube, which extends down to the floor of the pelvis. I use a ten-per-cent. iodoform-gauze. I have never seen iodoform-poisoning after packing the abdominal cavity with iodoform-gauze.

Formerly, I was more willing to operate during the attack than I am now. My feelings have changed because now we can offer the patient an operation without danger of hernia, if done between the attacks, and this, in addition to the other advantages of the intermediate operation, has led me to prefer it, and to always endeavor to obtain it.

What is the cause of death in appendicitis? In the acute cases, in which operation is done as soon as the diagnosis is made, it is very rare that the result is fatal. This is true of operations in the hands of all operators who have reported their cases. Also when done in the intervals of attacks, operations are enormously successful. Judging from the results, this operation seems like a light and easy thing. Operations done on patients after two or three, or even four attacks, are very successful. When an operation is undertaken on a patient who has suffered from very numerous attacks of inflammation, when there are adhesions and broken-down tissue to embarrass the surgeon, and to increase the risk of sepsis, we get an occasional bad result.

The chief cause of death is, therefore, delay of one sort or another. If the cause of death be general septic peritonitis, this comes late in the attack, and after the time when a good diagnostician should have recognized the disease; therefore, had there been no delay, there would have been no septic peritonitis, which is, as you know, one of the principal causes of death in appendicitis. In the cases which have gone on to the formation of abscess, each day's delay increases the difficulty and the danger of an operation, which at first might have been easy and safe, so that finally it may become an impossibility. Again, then, *delay* is the principal cause of death.

After an abscess has formed, the proper time to operate has given rise to considerable discussion. Treves, for instance, maintains the view that when suppuration has been walled in, the longer one waits before operating the nearer the pus will come to the surface. This is, in my opinion, an unscientific and unwarranted statement, because instead of approaching the surface the pus may be traveling upward toward the liver or downward into the pelvis. My own opinion is, as I said before, that in abscess-cases the sooner the operation is done the better. In such cases, if the appendix has not yet softened and broken down, and where only a small area of the peritoneum has become involved, the organ can be easily removed in most instances; but in older cases, where we meet with more advanced peritonitis, with adhesions and

formation of much pus, the softened and broken-down appendix may be unrecognizable, or if recognized it cannot be safely handled or removed. An abscess opening into the gut results in one of two ways: either the disease is cured, or the appendix remains and another abscess is set up, which may discharge in the same way. I would not operate in such cases unless the abscess recurred.

This brings us to the question of the removal of the appendix in every case. A discussion upon this point has been carried on in Philadelphia, and many operators hold that the organ should always be searched for until found and then removed. In point of fact, in some cases the appendix cannot be found; it may be hidden by a thick and more or less impenetrable wall of inflammatory tissue, and when this happens, it is frequently better to give up the search for fear of making an opening into the intestines. In many cases, too, the search will consume too much valuable time, and may lead to needless and dangerous enlargement of the wound. If the wound is thoroughly cleansed and free drainage established, little is to be feared from remnants of the appendix left in the body. If such a piece of tissue gives rise to trouble and sets up an abscess it can be operated upon secondarily. I remember a case in which death followed an ill-advised search for the appendix. An abscess-cavity about three inches in diameter had been opened, but the general peritoneal cavity was intact. As the operator did not discover the appendix, he took a sponge and so vigorously wiped the abscess-wall that he broke it, and through this rent a loop of intestine protruded and immediately drew back into the abdomen, but in that instant it had become infected, and it gave rise to a fatal septic peritonitis.

As to the sequelæ of the operation. I have not found fecal fistula so serious a complication as I feared it would be. Nearly all of these fistulæ close spontaneously. The escape of a little feces is not usually dangerous. Where these fistulæ will not close, if anything is to be done it should be done very deliberately and carefully. The only safe procedure is to enter the peritoneal cavity at some other point than through the fistula. If the fistulous opening is enlarged the intestine is pretty sure to be wounded, but an opening, say a little above the fistula, is safe and easy.

Continued Fever.—Dr. Parson reported to the Royal Academy of Medicine in Ireland a case of typhoid fever in which the attack occupied a period of 290 days. After hearing his detailed account of the patient's condition from onset to recovery, the members agreed with him in pronouncing it a case of genuine typhoid fever, with perhaps an undiscovered complication.

TUBERCULOSIS IN INFANCY AND EARLY CHILDHOOD, WITH SPECIAL REFERENCE TO THE MODE OF INFECTION.[1]

By L. EMMETT HOLT, M.D.,
OF NEW YORK;
PROFESSOR OF THE DISEASES OF CHILDREN IN THE NEW YORK POLYCLINIC.

It is not many years since tuberculosis was thought to be a rare disease in infancy; but we now know that it is quite as frequent as at any other period of life, and probably even more than this. While not common in private practice, tuberculosis in hospitals and institutions is to be ranked among the common infectious diseases.

In 500 autopsies made upon children in Munich, Müller found lesions of tuberculosis in forty per cent. This, I believe, is a far greater proportion than is seen in the institutions of this country. In 1045 consecutive autopsies, from the records of the New York Infant Asylum and the Babies' Hospital, tuberculosis was found in but ten per cent. of the cases, the number being somewhat higher (fourteen per cent.) in the Babies' Hospital, where only sick children are received, than in the Asylum (eight per cent.), where this was not the case. The observations which I shall present are based upon a study of these autopsies, to which are added 17 made elsewhere, or 119 in all. Of these cases, 57 died during the first year, 39 during the second year, 32 between the second and fifth years, and only 15 were over five years old. In the following table are given the visceral lesions that were found:

THE FREQUENCY OF THE VISCERAL LESIONS IN 119 AUTOPSIES UPON TUBERCULOUS CHILDREN.

Organs.	Number of Cases.	Per Cent.
Lungs	117	99.0
Pleura	69	58.0
Bronchial lymph-nodes	108	96.0
Brain	40	37.0
Liver	77	65.0
Spleen	88	75.0
Kidneys	46	39.0
Stomach	5	4.0
Intestines	40	37.0
Mesenteric lymph-nodes	38	35.0
Peritoneum	10	9.0
Pericardium	7	6.0
Endocardium	1	0.8
Thymus	3	2.5
Suprarenal capsules	2	1.7
Pancreas	3	2.5

Infection of a child with tuberculosis may take place through the skin, through a wound which has been accidentally inoculated, through the eyes,

[1] Part of a paper read at the New York Clinical Society, November 27, 1896.

through the placental circulation in intra-uterine life, and through the alimentary or respiratory tract.

Primary tuberculosis of the skin in young children is so rare that it may be dismissed with a mere mention. As examples of wound infection may be mentioned the bite of a person suffering from tuberculosis, or the rite of circumcision performed by one who has the bacilli in his saliva. The latter is known to have produced tuberculosis in a number of well-authenticated cases.

Intra-uterine Infection.—This was not demonstrated in any of my own cases, although I think it highly probable in all of the cases, five in number, which died during the first three months of life. Three of these were under two months old, one being but twenty days, and two but seven weeks old. The child who died on the twentieth day was born prematurely of a mother who was suffering from advanced tuberculosis. The mother died shortly after the child; the autopsy showing in her case, besides the lesions of general tuberculosis, a tuberculous endometritis. The child had cheesy bronchial glands, and miliary tubercles and small tuberculous nodules in the lungs, but none in the alimentary tract, the spleen, or the liver. That lesions were not found in the liver may be thought to be rather against infection through the placenta; but not necessarily so, for in several of the congenital cases bacilli in numbers have been shown by animal inoculations to be present both in liver and spleen, though no tuberculous lesions were found. They may also readily reach the lungs through the ductus venosus and vena cava, without passing through the liver. In one of the children, dying at the age of seven weeks, cheesy nodules were found in the lungs and in the spleen. In the other dying at this age, the mother was suffering from advanced tuberculosis, and died eleven days after the birth of the child. At four weeks old, when it was first seen, the child weighed but three pounds. The autopsy showed an extensive tuberculous pneumonia, with cheesy bronchial glands and tuberculous deposits in the spleen, liver, intestines, and mesenteric glands.

Aside from the observations which have been published regarding tuberculosis in calves born of tuberculous cows, intra-uterine infection through the placental circulation has been demonstrated in the human race by the cases of Birch-Hirschfeld, Lehmann, Bar and Rénon, and others. In Birch-Hirschfeld's case,[1] the organs of a fetus taken from a woman dying from general tuberculosis were found to contain tubercle bacilli, although no tuberculous lesions were present; bacilli were also found in great numbers in the placental tufts. In Lehmann's case[2] there were tuberculous lesions in the placenta as well as in the child's organs. Bar and Rénon[3] made inoculations in guinea-pigs with the blood drawn in five different cases from the placental extremity of the umbilical vein, where women with advanced tuberculosis were delivered either of living or still-born children. The results of these injections were negative in three cases, and positive in two. In one of the latter the child was still born, although living the day before birth. No tubercle bacilli could be discovered with the microscope in any of the child's organs, but they were shown by inoculation in animals to be present in the spleen, liver, and peritoneal fluid. In their second positive case, the child lived for forty days and died of acute bronchopneumonia. No report of an autopsy upon the child is given in the abstract of their paper (I have not had access to the original). The placenta appeared normal, but contained bacilli, as was demonstrated by animal inoculations.

From all these cases it would appear that the child often escapes even though the mother may be suffering during pregnancy from active tuberculous disease. With latent disease the chances of such infection of the child are certainly small.

In most of the cases where children die of tuberculosis during the first two or three months of life, I believe the probabilities to be very strongly in favor of intra-uterine infection. In all later cases, however, it is much less probable than that infection occurred subsequent to birth.

Infection through the Alimentary Tract.—The source of primary infection of the alimentary tract may be either the milk of a tuberculous nurse, or tuberculous cow, or tuberculous meat.

All of these I believe to be extremely rare. Their importance in the etiology of tuberculosis in infancy I think has been very greatly exaggerated. In the series of autopsies above given, there was not one in which a careful study of the lesions made it at all probable that the primary lesions were of the stomach or intestines, and in sixty-three per cent. of these cases the intestines were not affected at all. In the cases where the stomach and intestines were the seat of tuberculosis, with very few exceptions, the disease has been only slightly marked in that locality, while very advanced in the lungs and bronchial lymph-nodes. The intestinal ulcers of tuberculosis in infancy are usually small and superficial and not numerous, as compared with those seen in children over two years old.

The great infrequency of primary infection through the alimentary tract is also shown by the experience of Northrup,[4] who, in a series of 125 autopsies upon tuberculous children, mainly infants, found but a single case in which the infection appeared to

have occurred in this manner, as against eighty-eight, in which it was clearly through the bronchial lymph-nodes.

That bacilli may pass the mucous membrane of the intestine without producing disease in it, is not impossible. I have been looking for years for a case where the mesenteric glands were manifestly tuberculous, without tuberculous ulceration of the intestine, and I have yet to find the first one. Often the ulcers have been so small and so few as to be discovered only by a most careful search, but, so far, some have always been found.

The intestines are more frequently the seat of tuberculous disease in older children than in infants, as is shown by the Reports of the Pendlebury Hospital of Manchester, England. In 131 autopsies on cases of tuberculosis in children, most of whom were over three years old, the intestines were involved in fifty per cent. of the cases, against thirty-seven per cent. in my own series of autopsies.

Considering how extremely susceptible are the intestines of infants to other forms of infection, this contrast is rather surprising. The explanation of the difference seems to me to be this: Intestinal infection is nearly always secondary to disease of the lungs. Infants usually die from the more rapid tuberculous processes in the lungs or brain before there has been time or opportunity for intestinal infection to occur. The opportunities for such infection depend upon the number of bacilli which are coughed into the pharynx and swallowed. In infancy this number is small, because so many die of tuberculous pneumonia or meningitis before extensive softening in the lungs has taken place. In older children the slower course of the pulmonary disease gives ample time for intestinal infection, while the more extensive softening and excavation are accompanied by discharge of a much larger number of bacilli.

Unless the udder is the seat of disease, the number of bacilli contained in cow's milk is so small that infection from this source can hardly be considered as anything more than a possibility. The same may be said of the milk of tuberculous women. From tuberculous meat, also, the danger is a very small one, as tuberculous deposits in the muscles are extremely rare. Bollinger was unable to induce tuberculosis in animals by feeding them upon the expressed juice of such meat.

In this connection, the following incident is interesting as bearing upon the other side of the question: Near a large American city was a fancy stock-farm of registered Jersey cows, which supplied milk for table use and infant-feeding to a large number of families in the wealthiest part of the city, for a period of over ten years. At the end of that time the tuberculin test was used for the first time, and forty-five per cent. of these cows were found to be tuberculous, and were killed by order of the State Board of Health. The diagnosis was confirmed by autopsies upon the animals in every instance. An investigation was instituted among the children who had been fed upon this milk, but in only one case of many hundreds could it be learned that tuberculosis had developed, and in this instance it was by no means established that the milk had been the source of infection. It should be stated that this was before the days of sterilizing milk for infant-feeding. Besides the families who took the milk in the manner mentioned, the employés at the farm were accustomed to drink the skimmed milk in large quantities daily as a beverage in place of water. Many of them continued to do this for years, and yet not one of them developed tuberculosis.

There is, I think, little doubt that tubercle bacilli, in small numbers, may be introduced into the stomach with the food almost with impunity, traverse the intestinal tract, and be discharged in the stools without ever attaching themselves to the mucous membrane. Unfortunately, those entering the respiratory tract do not have such a ready means of exit.

Considering the susceptibility of the intestines in infancy, the fact that in sixty-three per cent. of these autopsies they were not involved at all, and that where intestinal lesions were present they were, with but few exceptions, slight, and that the marked cases were usually, I think in every instance, associated with extensive breaking down of a tuberculous pneumonia, the conclusion seems warranted that primary infection of the intestines in infants and young children is among the very rare occurrences in medicine, and that conditions exist in the alimentary tract, in consequence of which the bacilli do not gain a foothold unless they are introduced in very great numbers, as happens as a result of cavity-formation in the lungs.

Infection through the Respiratory Tract.—A study of the lesions of infantile tuberculosis, as shown in the table given in the beginning of this article, proves, it seems to me, conclusively, that infection almost invariably occurs through the respiratory tract. In ninety-nine per cent. the lungs were diseased, and in ninety-six per cent. the bronchial lymph-nodes. The mucous membranes of the respiratory tract in infancy and early childhood furnish conditions even more favorable for infection than those of adults. It is by breathing an atmosphere containing tubercle bacilli that most infants get the disease. The following example of direct transmission of the disease through the respiratory tract is cited by Reich,[5] and is one of the most striking illustrations on record of the ex-

treme susceptibility of infants to infection through this channel: In a town of about 1300 inhabitants the obstetric practice was divided between two midwives. Within fourteen months no less than ten infants, who had been delivered by one of these women, died of tuberculous meningitis. In none of these families was there a history of tuberculosis. This midwife was found to be suffering from pulmonary tuberculosis, and died from that disease. It was her custom to remove the mucus from the mouth of the newly born infants by direct mouth-to-mouth aspiration, and then to establish respiration by blowing into the nose. In the practice of the other midwife, who was healthy, no cases of tuberculosis occurred, although she treated the newly born infants in the same fashion.

The bacilli entering with the inspired air may be arrested either upon the mucous membrane of the upper or lower respiratory tract—in infancy usually the latter. They may induce disease in the walls of the finer bronchi, or may pass through to the lymph-nodes, where they may be for the time arrested. The lungs are affected in a large number of cases, probably in the majority, secondarily to the involvement of the lymph-nodes. Sometimes this takes place by direct extension, through contiguity; sometimes by the opening of a small bronchus or blood-vessel by ulceration, whereby the bacilli are rapidly disseminated through the lungs.

The important part played by the bronchial lymph-nodes in tuberculous infection of the lungs has been understood for some time. It was well brought out in an admirable paper by Northrup[4] in 1891.

It is not the purpose of this paper to show that there is no danger of tuberculosis through milk. I believe most strongly that all cows whose milk is used for food, whether for infants or older children, should pass the tuberculin test; and further, that when the milk-supply is from a doubtful source, milk should be heated to a sufficient degree—167° F.—to destroy such bacilli, should they be present. But when this source of danger has been entirely removed, I believe we will have accomplished very little in the prevention of tuberculosis.

Vastly more important is the enforcing of stringent rules regarding the isolation of persons with active tuberculosis, both in the home and the hospital, the careful destruction of the bacilli in the sputum from such cases, the disinfection of apartments after attacks, and most of all the early diagnosis of the disease in all persons who are brought into close contact with children, whether as nurses, teachers, or companions.

CONCLUSIONS.

1. Intra-uterine infection in cases of tuberculosis is very rare, the child often escaping even when the mother is suffering from active disease in an advanced form.

2. Infection through the alimentary tract is also very rare, and will not explain more than one or two per cent. of the cases.

3. The distribution of the lesions in tuberculosis of infancy and early childhood points conclusively to infection in the vast majority of cases through the respiratory tract.

UTERINE FIBROIDS COMPLICATED BY PREGNANCY.[1]

BY A. VANDERVEER, M.D.,

OF ALBANY, N. Y.;
PROFESSOR OF DIDACTIC, ABDOMINAL, AND CLINICAL SURGERY IN THE ALBANY MEDICAL COLLEGE.

FOR many years careful obstetricians, consulting gynecologists, and general surgeons have witnessed the disappearance, in many instances, of uterine fibroids during the course of pregnancy; absorption has taken place beyond a doubt. Again, many have been the cases in which suppuration has occurred, and patients have died as a result of septic conditions, the source of which at the present time could have been reached and treated with success. There are, perhaps, few conditions that give the family physician so much anxiety as those of fibroid, in which the patient becomes pregnant. On the other hand, there is perhaps no class of cases that gives the abdominal surgeon so much cause for thought as the cases of fibroid in which there has been a marked reluctance on the part of the patient to submit to an operation, and yet in which there is sudden enlargement with suspicion of pregnancy, such as existed in the two cases I have to report. In these cases it was apparent to the patients and their friends that delay was not admissible, the chances for the patients' recovery resting entirely upon an early operation.

To-day we approach such conditions with a sense of assurance that they are amenable to surgical interference, and that the recovery of the mother is certain in a large percentage of cases. And yet text-books do not refer to these cases with quite that emphasis that the conditions seem to demand.

Davis, in his recently published work[2] says:

[1] Read at the Second Pan-American Medical Congress, held in the city of Mexico, November 16, 17, 18, and 19, 1896.

[2] "Treatise on Obstetrics," p. 28.

"Pregnancy may occur in a fibroid uterus, and in such a case a most careful examination is required to detect the fact. It will usually be necessary to examine the patient under an anesthetic, and to map out carefully, if possible, the condition complicating the pregnancy."

Courty[1] makes the following convincing statement:

"There is no doubt that the presence of myomata diminishes the number of conceptions and increases that of abortions and miscarriages. Whether the presence of the fibrous tumor prevents the free development of the uterus, or whether it determines hemorrhage, it often causes abortion. Delivery may be impossible; it is always difficult, dangerous, and complicated, and it exposes to troublesome consequences. According to Tarnier, out of 42 cases delivery only terminated spontaneously 8 times; it required the use of forceps 6 times, version 6 times, induction of premature labor once, embryotomy once, enucleation of the tumor once, and Cæsarean section 14 times; the malady caused death 5 times before delivery (of these 42 patients only 13 were cured)."

I also quote from Mann[2] as follows:

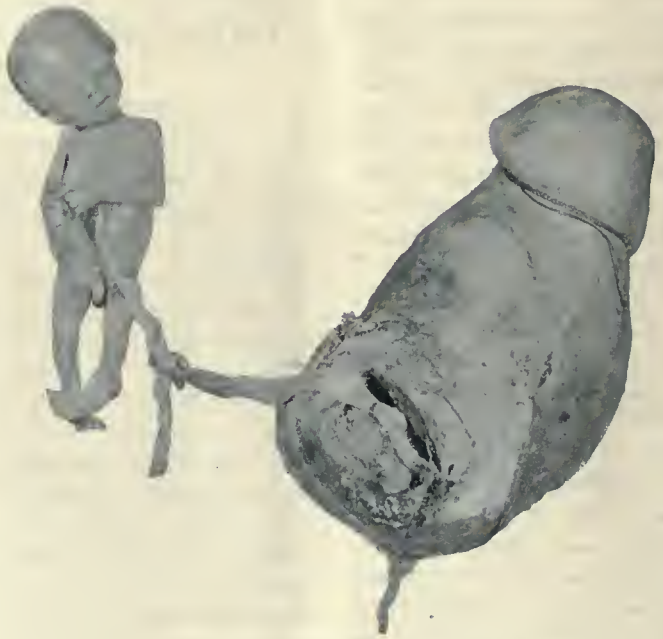
"Pregnancy and labor are occasionally complicated by the existence of fibromyomata. The preservation of the life of the mother may depend upon the removal of the growth, the induction of premature labor, or Cæsarean section. Dr. Jas. R. Chadwick has published in a paper read before the Massachusetts Medical Society, at its annual meeting in June, 1895, a report and summary of 10 cases of pregnancy and labor complicated by existing fibromyomata. Of these cases, 1 miscarried, 2 died, and 7 recovered; in all of the 7 cases of recovery, the tumors were subperitoneal. The question of surgical operation for removal of these tumors during pregnancy is not a very difficult one to solve. When the tumor is subperitoneal and pedunculated, pregnancy is not a barrier."

[1] "Diseases of the Uterus," p. 634.
[2] "American System of Gynecology," vol. ii, p. 590.

It is to be observed that the subperitoneal and pedunculated varieties give comparatively little trouble in cases of pregnancy, and this may be said of the pedicled or sessile subserous fibroma, as the following extract from Pozzi[1] confirms:

"Pregnancy gives a lively impetus to the development of fibrous tumors, and often causes their edematous softening. The treatment depends upon the nature of the symptoms, and the seat of the tumor. If it is a pedicled or sessile subserous fibroma of the fundus, we may hope that it will not interfere with the course of pregnancy. If there is danger of inflammation or the transformation of the tumor into a fibrocyst, there is also a hope that it will disappear during the uterine involution, and we may therefore pursue the expectant treatment. In the case of pelvic fibroids, however, delay seems more dangerous; if they cause no very serious symptoms we may wait in the hope that they may either precede the fetal head at the time of parturition, as has been observed, or else will ascend above the superior strait after the rupture of the membranes. Often the labor is accomplished only after a duration which results in a fatal exhaustion, if the woman does not die at once of the hemorrhage. These risks decidedly limit the advisability of the expectant method."

FIG. 1.



Case 1. Lower segment of uterus containing fetus, opened.

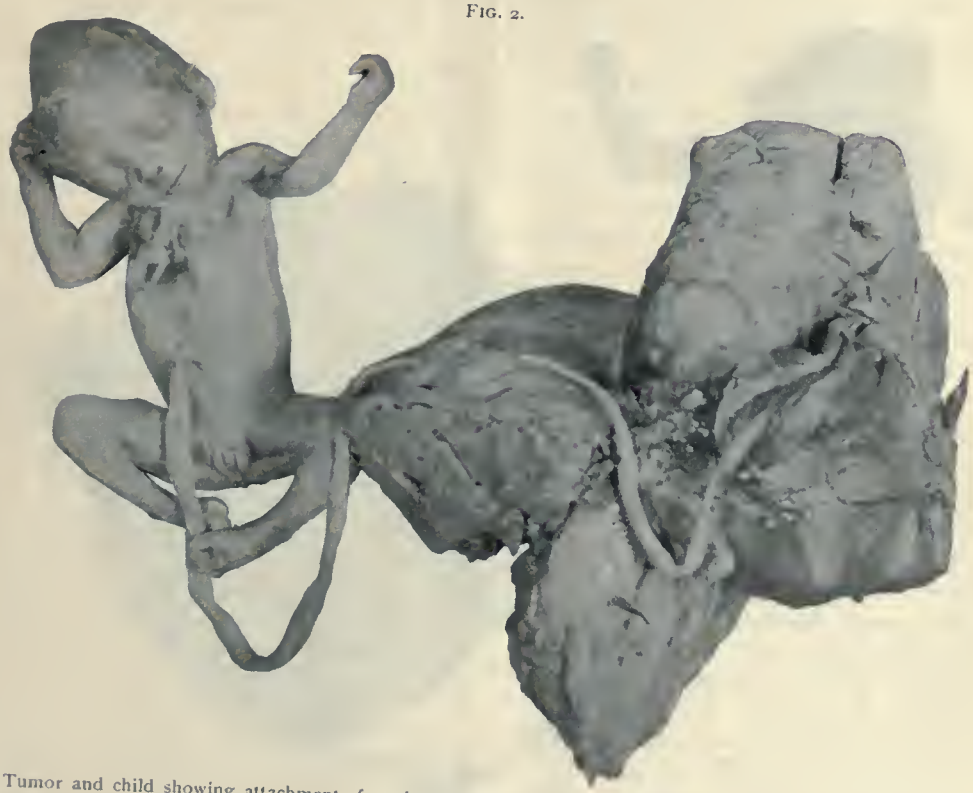
These few extracts illustrate the dangers that present themselves to the obstetrician in cases of fibroids that interfere with the cavity of the uterus, or obstruct the outlet of the uterus or pelvis. I am indebted to Dr. Rosenwasser of Cleveland for some statistics presented in a recent paper.[2] He says:

[1] "Medical and Surgical Gynecology," vol. i, p. 327.
[2] "Report of Three Cases of Uterine Fibroids Complicated by Pregnancy," by M. Rosenwasser, M.D.

"Of 228 cases of labor complicated by fibroids, collected by Güsserow,[1] more than one-half of the mothers and two-thirds of the children died. The assumption that many of these deaths may have been due to meddlesome interference on the part of the obstetrician is contradicted by Güsserow's[2] carefully compiled tables. Among 147 cases of labor, collected by him, 78 mothers died. Of the 61 mothers requiring manual or instrumental aid, 33 died. The remaining 45 deaths were therefore among the 86 cases not interfered with. The labors allowed to go to a natural termination were undoubtedly those in which there was the least hindrance to delivery, and yet they ended as fatally as did those subjected to delay, injury, and sepsis. In the more recent statistics, collected by Stately,[3] there are 597 cases in which no interference occurred before labor. Of these 220, or 37 per cent., died. This reduction in the mortality is owing to the improvement in technic within the last ten years. Among 307 cases reported as having aborted, the death-rate was 12 per cent."

It would seem, then, that surgical interference, either by myomectomy or by hysterectomy, is followed by more favorable results than is gathered from the statistics above quoted. The number of cases thus treated is, however, as yet insufficient to enable us to formulate any fixed rules for general guidance. Each case must be considered on its own merits, and must be managed in accordance with the best interests of the mother, and, where possible, also of the child. Whenever the location of the tumor is not likely to interfere with delivery, or its moderate rate of growth will admit of delay until after the viability of the child, a conservative course is clearly indicated. Myomectomy in the interests of the child is justifiable in cases in which dystocia would become a strong probability. At or near term in event of obstruction to delivery, suprapubic hysterectomy is probably the safest course. The loss of mothers ought not to exceed ten per cent.; the children ought nearly all to be saved.

FIG. 2.



Case 2. Tumor and child showing attachment of cord to lower segment of the uterus—the tumor extending into right lumbar region laid open.

Dührssen's proposition[1] to deliver the child by vaginal Cæsarean section, and then to preserve the uterus, or remove it as the nature of the case might indicate, has yet to be put to the test of experience.

The two following cases are good illustrations of uterine fibroids complicated by pregnancy as met with at times in our surgical practice, and bring out strongly the points to which I wish to refer; they emphasize the necessity of thorough operation in a certain class of patients. Delay, in the hope of absorption, or in the hope of delivering a living child, can scarcely be tolerated.

[1] "Der vaginale Kaiserschnitt," Dührssen, Berlin, pp. 27–33.

CASE I.—Mrs. X. came under my observation in August, 1893, with a history of continuous and severe uterine hemorrhage during the two preceding months. Treatment was readily agreed to, and in October, 1893, I removed an intra-uterine polypus without trouble, and carefully curetted the cervix and cavity of the uterus. After this she became absolutely regular in her menstruation, and improved decidedly. At the time of operation I discovered that she had an interstitial fibroid connected with the anterior wall of the uterus. She had borne several children, and had had no miscarriages. She was then forty-five years of age. The case progressed so favorably that no further examination was made until January 24, 1895, when I was greatly surprised at the size of the abdomen, and found a hard mass in front, plainly the fibroid connected with the anterior wall of the uterus, which had increased very markedly in size. On the right side, and extending up into the right lumbar region, was an additional mass much larger than a child's head, which gave the feeling of fluctuation, and led to the supposition of its being an ovarian cyst. There was also to be felt deep down in the pelvis, by pressing the abdominal tumor well over to the right, a small mass that I believed to be the left ovary, and which fluctuated. She had had some trouble in getting her bowels to move, yet the constipation was relieved by proper laxatives. Her menstruation had ceased in September, 1894. She positively declared that she could not be pregnant, yet her husband felt there was a possibility of such being the case.

The patient's condition was such that it was not safe to wait longer before resorting to operative interference. The patient was becoming somewhat emaciated, pressure upon the stomach was interfering with digestion, and she was growing nervous and worried as to her condition. An eminent gynecologist saw her in consultation with me, and after two careful examinations announced that we had to deal with a uterine fibroid, with probably a double ovarian cyst, and that she could not be pregnant. There was an entire absence of any condition of the breasts indicating pregnancy, and at no time had she been nauseated. It is true that there was a slight port-wine discoloration to be noticed about the mucous membrane of the vagina, but the neck of the uterus could be distinctly made out, it was not dilated or softened in the least, and there was no discharge that gave us any strong impression of pregnancy.

FIG. 3.

Case 2. Same as Fig. 2. Showing the posterior view of the uterus—the tumor connected with the fundus laid open.

Operation was decided upon and performed March 18, 1895. I found on opening the abdomen a large uterine fibroid. The mass that extended up into the lumbar region was but a prolongation, and had commenced to soften, cystic degeneration taking place. The immediate steps in the operation were those of supravaginal hysterectomy, for what I believed to be a large fibrocystic growth. Each ovary

was about the size of a turkey's egg, and cystic in character. The lower segment of the uterus could be distinctly mapped out from the fibroid and its associate cystic degeneration, and on lifting the entire mass from the abdominal cavity, using the rubber tube for constriction, I did a complete supravaginal hysterectomy, making use of the Koeberle serreneud. As I removed the mass I realized that in making the section through the cervix, the incision had passed just below the membranes and amniotic fluid of a pregnant uterus. After proper care of the pedicle and closing of the abdominal incision, I found on examining the specimen a fetus of nearly four months' growth in connection with the fibroid tumor. There was nothing particularly eventful in the case afterward. The patient made an uninterrupted recovery, and has remained in the best of health since.

CASE II was quite impressive. Mrs. E. S., aged thirty-five, had been married a little more than a year, but had had no miscarriages during that time. I saw her April 1, 1896, in consultation with her family physician, Dr. Wm. H. Bailey. She had been in a state of perfect health for a period of twenty-two years; menstruation had been regular, never painful, and had begun at the age of thirteen. She believed herself to be pregnant, although for the past year she had menstruated at irregular intervals. She had made all her preparations for confinement, supposing herself to be near the time of delivery. Her physician had said frankly to her that if she were pregnant he believed she also had an abdominal tumor, yet she did not wish an examination, and declined it, being so firmly impressed with the belief that she was pregnant. When I saw her the abdomen was so tense that it was almost impossible to make out a correct condition of affairs. The left side of the abdomen presented a somewhat irregular, lobulated appearance, and felt exceedingly hard in certain places. The right side gave a more distinct appearance of an ovarian cyst. The patient had a pulse of 110, temperature ranging from 100° to 102° F., and she was vomiting quite constantly; there was some trouble in getting her bowels to move, and she was decidedly sick. I expressed my opinion that while there was a possibility of her being pregnant, I believed it was a case more particularly of uterine fibroid, possibly associated with ovarian cyst. Her breasts presented a negative condition as to pregnancy, and so did the neck of the uterus and the vagina.

An operation was decided upon and performed April 4, 1896. A large fibroid, multiple in character, was found, the details of the operation being almost precisely as in the previous case, a well-developed fetus of four months being present. The patient made a good recovery, the only marked symptom presenting in the after-condition being a decided delirium, that came on during the fourth day and continued nearly a week, which I attributed to her very anemic condition. Since the operation she has gained over twenty pounds in flesh, and presents a picture of health.

These two cases but a few years ago would have been beyond the reach of surgery. Such patients ought now to receive the prompt attention of the abdominal surgeon. It is possible that in some cases the living child, at full term, may be saved. There should be no hesitancy in removing the entire uterine appendages, although the tumor may be much smaller than in either one of the cases here reported. If left to themselves, and the attempt made to do a Cæsarean section, suppuration may follow and septic conditions result in the loss of the patient. I am most emphatic in my belief that in cases of uterine fibroid, with suspected pregnancy, a careful, thorough examination should be made, and if there is a doubt as to the possibility of delivering the patient at full term, an early radical operation should be done.

It will be noticed in these two cases that the fetus occupied the lower segment of the uterus, and yet neither patient gave symptoms of an approaching abortion, although Case 2 was rapidly reaching a fatal termination. It is true that neither one of these cases illustrates very positively the course we should pursue at a time when viability of the fetus presents. We may possibly, as we do sometimes in cases of retention of urine, change the position of the fibroid, particularly if it is not large, or if it is not growing rapidly, so as to relieve the pressure, and development may go on to full term, when the child can be delivered, the tumor being of such a character that contraction takes place, and the mother and child live; but we all know of, and have had experience with, the dangerous hemorrhage that results at such a time, in some of these cases; we know of the lamentable record of prolapsus of the cord, constriction of the thoracic viscera, rupture of the uterus, and local, and sometimes general, peritonitis, with all the complications of adhesions to the intestines and omentum, so that even though the child may be viable we must consider the advisability of recommending an operation at this time. Certainly, before viability is reached, we need not hesitate as to the course to be pursued, particularly when the evidence of constant enlargement of the tumor is present.

In the discussion of this subject it is my desire to emphasize somewhat the exclusion of the question of small tumors. It is only to the large ones, such as grow rapidly under the impetus of pregnancy, that I wish to call your attention. These cases left to themselves present a very high rate of mortality. They do not admit of myomectomy. A uterus with such large fibroids, and with cystic degeneration going on, will not admit of the patient going to full term; the condition demands prompt radical surgical interference.

GLAND-FEVER.

By HERBERT B. WHITNEY, M.D.,
OF DENVER, COL.:
PROFESSOR OF CHILDREN'S DISEASES AND OF PHYSICAL DIAGNOSIS IN THE STATE UNIVERSITY OF COLORADO.

Under this name—*Drüsenfieber*—a condition was first described by Pfeiffer[1] in 1889 which seems, clinically at least, to represent a new pathological entity. Its chief characteristic is a very considerable, and often painful, swelling of the cervical glands, accompanied by fever; an acute adenitis, which pursues a quite definite course, and always ends in resolution. Since Pfeiffer's first article further cases have been reported by Heubner, Starck,[2] Protassow,[3] Filatow, and Moussous.[4] Within certain limits all these reported cases appear to fit into the same frame: they bear a sufficiently strong resemblance to each other to justify their classification under the single term, "gland-fever," while, on the other hand, it would be very difficult to regard them as varieties of already recognized affections.

Having recently observed two, and possibly three, cases of this disease, I shall make a condensed *résumé* of them a basis for a brief statement of what is already known or surmised about this affection.

Case I.—Edna P., aged two years and six months, had always been a robust child, and was never ill. I was first called on April 6, 1896. The history stated that the child had not seemed quite well for a week, but there had been no complaint of the throat or of anything more than general malaise. On the day previous, April 5th, fever had been noticed for the first time, and also a swelling just beneath and behind the ears. I found the child up and about, but with flushed face, rapid pulse, and a rectal temperature of 103° F. On each side of the neck, the lymphatic glands along the posterior border of the sterno-cleido-mastoid muscle were markedly swollen. These enlargements extended from the mastoid process to the clavicle, but the swelling was much more marked just below the ears, as may be inferred from the fact that the neighbors had made a unanimous diagnosis of mumps. The glands were discrete, without redness, and not noticeably painful on pressure. There were marked anorexia and constipation. With the exception of a very considerable infection of the fauces, a careful examination, including chest, abdomen, and ears, was negative, and remained so throughout the entire course of the affection. There was no initial vomiting, no cough, no apparent headache, and no stiffness of the neck.

For seven days the afternoon temperature was constantly from 102° to 104° F., and the glands, after having increased somewhat during the first forty-eight hours of my observation, remained unchanged. Frequent examination of the fauces disclosed nothing beyond the redness seen at the first visit. The child was only moderately ill; in the morning it played about as usual, but in the afternoon it was inclined to be quiet and drowsy. The anorexia and constipation persisted.

On February 13th the temperature had fallen to normal. For some little time the child was unusually pale, but otherwise it seemed little reduced. Its general convalescence was rapid. There was no noticeable emaciation. The glands had already become smaller when the fever ceased, but for six weeks afterward they could still be felt. The child has since been in perfect health without a day's illness.

Case II.—Paul S., aged three years and four months, had never had any acute illness, but about six months ago had been operated upon for enlarged tonsils and adenoid growths.

This child was brought to my office with a history of fever and glandular swelling during the previous two or three days. For a week previous he had seemed to be in poor health, though nothing definite had been noticed. The present attack had begun with vomiting, which was followed by fever and the coincident appearance of swellings in the neck. The appetite was gone, the neck was painful, and the head was held slightly twisted toward the left. There was no cough, and no complaint had been made of the throat.

On physical examination it was noted that the child was unusually pale and seemed weak, although still able to walk about. The rectal temperature was over 102° F. The glands along the posterior border of the sterno-mastoid were found to be considerably swollen on both sides of the neck, the largest being about the size of a hickory-nut, and situated just below and behind the left auricle. The throat was slightly reddened, but with this exception the result of the examination was quite negative.

Having recently attended Case I, and feeling confident as to the probable diagnosis and outcome of the affection, I gave the child a preparation of iron, and told the parents to keep him confined to the house, and to report again in a few days. I did not see the child again until the 21st. The glands were still swollen, though not so much as before. I was informed that the fever had continued steadily since the 9th, and the rectal temperature was found to be still several degrees above normal. The boy had not been confined to bed, but there had been complete anorexia, considerable emaciation, and much general debility.

He was again brought to me on the 24th with the statement that he seemed better in every way, and had begun to eat. The glands were still moderately enlarged, but the temperature was now normal after a continuous elevation for about two weeks. From this time on there was steady improvement, and in the course of a few weeks the glandular enlargement had entirely disappeared. The mother tells me, however, that convalescence was slow, and that it was many weeks before the child had wholly regained its original color, strength, and weight.

A third observation belongs, I believe, in the same

[1] *Arch. für Kinderheilk.*, *Bd.* xxix, *Heft* 3 and 4.
[2] *Ibid.*, *Bd.* xxxi, *Heft* 4.
[3] *Ibid.*, *Bd.* xxxi, *Heft* 4.
[4] *Jour. des Mal. de l'Enfance*, June, 1893.

category, although but few data can be given, and much doubt is permissible as to the diagnosis.

CASE III.—Ludlow F., aged two years, had been ill and under the care of a homeopathic physician for two or three weeks before I saw him. I could obtain a history only of irregular fever, much general weakness and depression, soreness and stiffness of the neck, and enlarged glands. He had always been a remarkably strong and vigorous child. I found the glands much swollen, precisely like those in the cases above reported, except that the tumefaction was much more pronounced upon the left. It should be added, however, that this child rapidly developed typhoid, while within a week after my first visit the glandular swelling had nearly disappeared. I am inclined to think that in this case an attack of genuine gland-fever was followed by typhoid; as to what relation could possibly exist between the two I am unable to conjecture.

The *etiology* of gland-fever is a study for the future. Undoubtedly the disease is infectious, and Pfeiffer says it is likely to affect several members of the same family, though no such tendency was seen in my few cases. Starck believes in the etiological importance of constipation, with resulting production of toxins. This theory does not accord with the comparative infrequency of the affection, nor with the fact that the cervical glands are always the earliest involved. In the majority of cases there has been some faucial congestion, and everything would seem to suggest this region as the probable seat of invasion. Age is evidently an important factor: the disease seems to be peculiar to the first decade, and all of my own cases were in patients under four years of age.

The only constant and characteristic *symptoms* of this affection are an acute and usually painful swelling of the cervical glands, together with a very considerable fever of from eight to fourteen days' duration. Anorexia and marked constitutional depression, with slow convalescence, are the rule. As frequent concomitants, are to be mentioned initial vomiting, a moderate congestion of the fauces, and obstinate constipation.

The glandular swelling is usually bilateral, although there is very frequently a marked predominance on one side. The glands involved are chiefly those along the posterior border of the sterno-mastoid muscle. In each of my own three cases the enlargement was especially marked just behind and below the lobe of the ear, so as to form a prominence quite noticeable on simple inspection. These swellings show no tendency to confluence, but remain throughout as separate, firm, and sharply circumscribed tumefactions of the individual glands. They also show little or no tendency to phlegmon or suppuration; they are, however, usually tender on pressure, and evidently sensitive to movements of the neck, as shown by the usual stiff carriage of the head and the occasional torticollis. The duration of the swelling is somewhat variable, but it rarely subsides with the fever, and from four to six weeks will probably elapse before the glands have wholly returned to their normal size.

Besides the superficial cervical glands, the occipital, submaxillary, and the sublingual, may also be enlarged, though they are rarely painful. Moussous[1] has observed two cases where the adenopathy had evidently extended into the thorax; enlargement of the tracheobronchial glands was manifested by slight dulness in the interscapular fossæ behind, and especially by a severe paroxysmal cough resembling that of pertussis. In each of these two cases deglutition was painful, and even the simple movements of mastication seemed to produce painful sensations in the swollen glands. As a rule, the adenitis seems to be limited to the neck, the glands of the axilla and groin being invariably spared.

The development of fever is frequently preceded by a prodromal stage of malaise and slight impairment of the general health, which may have lasted a week. Coincidently with the appearance of glandular swelling there is an abrupt rise of temperature to 102°–104° F. An initial attack of nausea and vomiting, as in scarlet fever, is a common occurrence; and although no complaint may be made of the throat, it will often be found on inspection to be red, and, perhaps, slightly swollen. The fever continues uninterruptedly for from eight to fourteen days: characterized by marked morning remissions, it discloses this type in the behavior of the child, who, comparatively bright and playful in the morning, becomes in the afternoon listless and apathetic. Headache is often complained of, the tongue is thickly coated, and in many cases an obstinate constipation persists throughout the whole course of the disease.

With the subsidence of the fever, which in the majority of cases is by lysis, there is an immediate improvement in appetite and general condition. At the same time it will be found, as a rule, that the child presents a degree of pallor, and a loss of flesh and strength quite out of proportion to the apparently mild character of the disease. In this respect one is reminded of influenza, and it is usually many weeks before the full measure of strength and vigor has been regained.

The *diagnosis* of gland-fever could rarely present any difficulties. The swelling is unlike that of diphtheria; it is most prominent high up near the auricle, instead of at the angle of the jaw. Still less easily could it be confounded with any of the more common forms of glandular enlargement, such as the

[1] *Loc. cit.*

scrofulous or the sympathetic. Scarlatina anginosa, with its tendency to the production of phlegmonous and suppurative inflammations of the anterior cervical regions, need hardly be considered. The difficulty of speech and stiffness of the neck might in a very young child suggest the possibility of retropharyngeal abscess, but such doubt would soon be resolved by digital examination. In short, it must be very easy in the great majority of cases quickly to reach the conclusion that this form of acute febrile adenitis is a primary and independent affection.

As to *prognosis*, these cases have hitherto invariably recovered, and it would seem as if danger could scarcely arise, except possibly in the event of tracheobronchial involvement.

No *treatment* other than purely symptomatic has as yet been suggested. My own two cases were treated by the local inunction of an iodin ointment (Iodi puri gr. iss, Potass. Iodidi gr. xv, Vaseline ʒ iiss) and the internal administration of iron. In many cases cod-liver oil and a short visit to the mountains or seashore would undoubtedly hasten convalescence.

COCAIN-ANESTHESIA.

By JOHN A. WYETH, M.D.,
of New York;
Professor of Surgery in the New York Polyclinic Medical School and Hospital.

Of the four or five hundred practitioners who each year attend the clinical course at the New York Polyclinic Medical School and Hospital, and witness demonstrations of cocain-anesthesia in the department of surgery, fully eight out of ten express surprise at the results, and frankly acknowledge that they cannot obtain such satisfactory anesthesia without using a quantity of cocain so large as to produce unpleasant and, at times, dangerous constitutional poisoning. The response to this acknowledgment is usually a diagram of the anatomy of the integument, explaining, first, that there is a great difference in the thickness of the skin in various parts of the body, it being from one twenty-fourth of an inch to even more than this in some parts, as in the palms of the hands and soles of the feet, while in other portions it is as thin as $\frac{1}{240}$ of an inch. Second, the diagram shows that the knob-like swellings or varicosities of the sensory nerve-fibrils *terminate in the cells of the Malpighian layer*, and the fact is thus demonstrated that the cocain should be injected into this layer, where the smallest quantity will produce the widest anesthesia. To throw a solution of cocain into the deeper corium or into the subcutaneous areolar tissue is a waste of material and time, and involves a certain amount of danger, especially if the solution is injected into the areolar spaces. Under these circumstances, it is merely an accident if a sensory nerve is caught in the injected area, and the operator is certain to throw the cocain into rich plexuses of blood-vessels, where it is rapidly absorbed and carried into the general circulation. In the Malpighian layer there is such a network of sensory end-organs that they are sure to come in contact with the cocain solution and be immediately paralyzed as to their conductivity.

In portions of the body such as the walls of the abdomen or the back, where the circulation cannot be temporarily arrested or impeded by the application of an elastic bandage, I proceed as follows: The area of the operative field is thoroughly cleansed after the well-known aseptic practice. I see that the syringe and needle have been boiled, and that they are perfectly clean. I use the all-metal syringe invented by Dr. Dennis, and the finest kind of a needle. The needle is carried obliquely through the epidermis until the point is in the Malpighian layer, just beneath the epidermis. Arriving at this point, I force out (and it takes considerable pressure to accomplish this) a measured, or, after much practice, an estimated half-minim of the four-per-cent. solution. This produces a little sense of smarting, which passes off almost as instantaneously as it appears. The epidermis and skin affected by this small quantity of cocain turn white at once, and immediately, with the needle still in position, with a sharp-pointed knife I make an incision from one-quarter to one-half of an inch in length, always as far as the anesthesia has spread. The needle is then inserted one-quarter of an inch from the first point, and another half-minim or one minim of the solution is forced out at the same level, and the incision extended. It is evident that, with from two to four minims of the solution, an incision one inch long may be made through the skin and corium into the subcutaneous areolar tissue. There can be no danger of cocain-poisoning by this method for any ordinary incision three or four or five inches long, because a large proportion of the injected solution escapes from the wound with the bleeding which follows the incision. The insertion of tenacula will enable the operator to dissect from one-half to three-quarters of an inch on either side of this incision. If it now becomes necessary, and this is not always the case, on account of the lack of sensation in the subcutaneous tissues, a weaker solution may now be used to great advantage, but it should be remembered that any solution thrown into this areolar tissue is apt to be absorbed.

In practically all cases for cutting through the skin I prefer a four-per-cent. solution of cocain, made in a saturated solution of boracic acid, in order to prevent the development of microörganisms

or septic fungi. My method is to use the Schleich *strong* solution, No. 1, which contains only 3 grains of cocain muriate to 3⅝ ounces of distilled water or saturated solution of boracic acid for the subcutaneous tissues. At times the *normal* solution will produce a perfectly satisfactory subcutaneous anesthesia, and six or eight drams may be used if necessary. The following are the Schleich solutions:

NO. 1, STRONG.

℞ Cocain muriate . . 0.2 (gr. iij)
Morphin muriate . . 0.025 (gr. ⅜)
Soda chlorid . . 0.2 (gr. iij)
Sterilized dist. water, or saturated solution of boracic acid, q. s. to 100 c.cm. (fl. ℥ 3⅜)

NO. 2, NORMAL.

℞ Cocain muriate . . 0.1 (gr. iss)
Morphin muriate . . 0.025 (gr. ⅜)
Soda chlorid . . 0.2 (gr. iij)
Sterilized dist. water, or saturated solution of boracic acid, q. s. to 100 c.cm. (fl. ℥ 3⅜)

NO. 3, WEAK.

℞ Cocain muriate . . 0.01 (gr. ⅙)
Morphin muriate . . 0.025 (gr. ⅜)
Soda chlorid . . 0.2 (gr. iij)
Sterilized dist. water, or saturated solution of boracic acid, q. s. to 100 c.cm. (fl. ℥ 3⅜)

In operating upon an extremity where the circulation can be retarded or controlled, in many instances I use the two-per-cent. solution after incising the skin, because I can control the introduction of the solution into the circulation. I have found that, after having operated on an extremity, when the tourniquet is loosened and the flow of blood reëstablished, a dangerous amount of cocain may be suddenly carried to the heart, and with a serious effect. Therefore I loosen the tourniquet for a period of three or four seconds, then readjust it for several minutes, and repeat this procedure. In this way I let in such a small quantity of cocain at one time that it is distributed over a wide area and produces no bad effect.

At a recent clinic I removed an inflamed and very sensitive papilloma from the sole of the foot (one of the most sensitive parts of the body). I applied the Esmarch bandage in figure-of-eight fashion around the dorsum and sole of the foot and the lower leg, not shutting off, but retarding the circulation. I then carried the point of the needle directly into the center of the papillomatous mass, injecting one minim of the four-per-cent. solution. There was a sharp, stinging pain from the puncture of the needle and presence of the solution, which passed away in ten seconds, leaving the part completely anesthetized. The injection was repeated in the proposed line of incision, using, in all, four minims of the solution, and an incision an inch long and half an inch from the center on each side was made, the neoplasm cut away deeply, and four silk sutures introduced without the slightest appreciation of pain.

CLINICAL LECTURE.

EXOPHTHALMIC GOITER; CHRONIC TONSILLITIS; CARCINOMA OF THE TONSIL; CHRONIC ENDOCARDITIS.[1]

BY E. FLETCHER INGALS, M.D.,
OF CHICAGO;
PROFESSOR OF LARYNGOLOGY AND DISEASES OF THE CHEST IN THE RUSH MEDICAL COLLEGE.

CASE I. This patient, a woman of twenty-six years, complains of palpitation of the heart and smothering sensations, dating from early childhood. The attacks of palpitation are occasionally followed by unconsciousness for a few moments. She is short of breath, more or less, all the time, and has a little disturbance of the stomach occasionally. When eight years of age she was confined to bed about three weeks with rheumatism. Two years ago she first noted a little enlargement of the right side of the neck, beneath the sterno-cleido-mastoid muscle, just above the clavicle. The growth is movable beneath the skin, and is lifted upward when she swallows. The pulse is 119. Her complexion is a trifle livid; she says it is somewhat darker than formerly.

Observing the eyes carefully, you will see about an eighth of an inch of the sclerotic above the lower lid when she is looking straight forward. Two symptoms in this case are quite distinct, *viz.*, enlargement of the thyroid and palpitation of the heart; and if the eyes have become prominent, as I think is the case, we have a third symptom of a group which is diagnostic of exophthalmic goiter. She is extremely nervous, and this is another symptom of this disease. The heart and lungs are normal, except that the heart is a little irritable. The prognosis of exophthalmic goiter is always doubtful, and the treatment is generally unsatisfactory. However, we may hope for some reduction in the size of the thyroid by remedies administered internally and by means of hypodermic injections. I would recommend as the most satisfactory internal treatment tincture of strophanthus, beginning with 5 minims three times a day, and increasing the dose gradually to 10 minims. I have seen three cases do well under this treatment, and as the majority of patients do not even get better, it is well worth a trial. Professor Brower has seen some remarkable results from this drug. Injections of from 15 to 30 minims of a five-per-cent. solution of carbolic acid in water may also be used at intervals of a few days. In giving the injections, make sure that the needle has penetrated the gland by having the patient swallow after it has been inserted, whereby it will be sure to move with the thyroid. The direction of the needle may be changed without completely withdrawing it, so as to deposit a few drops of the solution in two

[1] Clinical Lecture held at Rush Medical College, Chicago, October, 1896.

or three different parts of the gland. Large doses injected in this way cause dizziness, and the amount should be limited so as to avoid undue discomfort.

CASE II.—This woman, twenty-seven years of age, has very little enlargement of the tonsils, but has had tonsillitis a number of times during the last two years. The glands are so small that it is impracticable to remove them with the tonsillotome. Such tonsils I have sometimes seized with vulsellum forceps and drawn into the tonsillotome for excision, but in several cases protracted hemorrhage has followed this operation, and I therefore prefer cauterization. A few applications will reduce such a gland to half this size, and with this reduction we are likely to get rid of the tendency to recurring inflammation. In cauterizing the tonsil, I use an electrode with platinum point, about half an inch in length, the current being regulated to heat it red in about a second. I press the full length of this point into the tonsil and make two or three cauterizations at each sitting. Where the gland is quite small, I cauterize without reference to the follicles, but where it is larger, the platinum point should be introduced into the follicles and moved about so as to completely destroy them. After cauterization the patient will use a gargle of a dram and a half of carbolic acid to a pint of water, hourly.

CASE III.—This man is a mechanic, sixty-seven years of age, who has been a smoker since his twentieth year. Up to the last five years he was also a heavy drinker. Nine weeks ago he began to have trouble with the throat, which he at first thought was due to a cold. It has not been severely painful, but feels sore, and he has occasional pains shooting up back of the ear. The pharynx is congested, the uvula is lengthened a quarter of an inch, and there is an ulceration with cauliflower-granulations extending over quite a large part of the left side of the palate and left tonsil, nearly an inch and a half in diameter. The only conditions likely to occasion chronic ulceration of the tonsil are tuberculosis, syphilis, and malignant disease. In tubercular ulceration we do not find cauliflower-granulations, there is usually not much redness or induration, and in the deep ulcerations, which are rare, the edges are pretty cleanly cut, though sometimes they are irregular. The superficial ulcerations have very irregular edges, and numerous smaller ulcers are usually found along the borders a short distance from the main ulcer. In tertiary syphilitic ulceration there is a sharp-cut border, the ulcer is gouged out, or the edge is undermined, but not everted. There is also a good deal of destruction of tissue, with considerable induration about it. In this affection we also expect to find other evidences of syphilis in the throat, and there are likely to be some enlarged glands in the neck. The pain may be slight or very severe. We may, therefore, exclude in this case both tuberculosis and syphilis. This disease is doubtless carcinoma of the tonsil, and it is spreading rapidly. There is less pain than usual, but it is increasing.

The prognosis is extremely unfavorable, and the treatment is absolutely unsatisfactory. He asks if I can help him without removing the growth. It is doubtful whether any operation will be of benefit, as complete removal is out of the question. Under the circumstances, I should be in favor of cauterizing with lactic acid, from fifty per cent. to full strength, as often as the patient will tolerate it. These patients are sometimes benefited for a time by the internal use of potassium iodid and arsenic, therefore these will also be ordered.

CASE IV.—This boy, seventeen years of age, says he cannot sleep more than two or three hours out of the twenty-four, and complains of getting out of breath on exertion. There is no cough, and the skin is pallid, cold, and moist. The pulse is 124 per minute, and so small I can hardly tell whether it is regular or not. Observe the puffy appearance of the face, particularly beneath the eyes, and notice that the lips are slightly blue. The feet and legs are swollen, and pit on pressure. Three years ago, rheumatism confined him to bed for a month and to the house most of the time for a year. Occasionally rheumatic pains have annoyed him since that time. From the appearance of the face and the lividity of the lips alone, we might almost conclude that the boy is suffering from some heart-affection. You will observe some bulging of the precordial region. Pulsation of the heart may be seen three inches to the left of the normal limit. The impulse of the heart is not strong, like the pulsation of hypertrophy, and a tremor is felt upon placing the hand over the apex. A distinct murmur is heard at the apex during contraction of the ventricles, and this is also heard to the left of the apex, but not above it. This murmur is systolic, and must be produced at the mitral valves.

The diagnosis is chronic endocarditis or valvular disease of the heart. The heart is dilated and the compensation poor. His treatment will consist of the administration of tincture of digitalis, minims 7½, three times a day after meals, and of tincture ferri chlorid, minims 10, ten minutes before meals.

CLINICAL MEMORANDUM.

INTUSSUSCEPTION IN A CHILD SEVEN MONTHS OLD; HIGH INJECTIONS; RECOVERY.

By W. P. NORTHRUP, M.D.,
OF NEW YORK;
PROFESSOR OF PEDIATRICS, BELLEVUE HOSPITAL MEDICAL COLLEGE; VISITING PHYSICIAN TO THE PRESBYTERIAN, WILLARD PARKER, AND FOUNDLING HOSPITALS; CONSULTING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

THE mother of this patient dropped into the office of her family physician, Dr. L. K. Neff, during his one-to-two o'clock office hours, to arrange for vaccinating the baby. So far as the mother knew, or the doctor observed, there was nothing amiss with the child. At three o'clock the baby went to sleep, awakening at five o'clock with a cry. "It had the colic," so it was said, and for that was given fennel tea, and brandy and water. After these doses the child vomited several times. The physician was called, arriving at six o'clock P.M., an hour after the first cry.

He at once examined the abdomen and discovered a sausage-shaped tumor lying along the margin of the liver.

No food was given that night, but the baby vomited twice. The bowels did not move.

On the following forenoon I found, with Dr. Neff, the same sausage-shaped tumor in the right hypochondrium. It was easily felt, and was three inches by three-fourths of an inch in size. The tumor began deep in the right flank, the left extremity being at about the median line. It was possible to explore the deep extremity with the end of the finger, and to feel a sharp shoulder.

The child tolerated examination very well; it lay in a stupor, relaxed as though under an anesthetic. No amount of manipulation caused change of countenance. The abdomen was flabby; the "sausage" could be mapped out, rolled about, and picked up between the thumb and fingers. Physical examination otherwise disclosed no abnormality; no digital exploration of the rectum seemed indicated, and, on account of the age of the child, none was made.

The diagnosis of intussusception was agreed upon. As yet there had been no passage from the bowels later than two normal movements, in the morning, before the occurrence of the first symptoms. The vomiting at first followed the giving of fennel tea and brandy, though it may be added it also occurred twice in the night. The symptoms thus far were two—pain and tumor. There was also a notable pallor, and a notable relaxation, though these are not urged as characteristic of the obstruction.

The plan of procedure agreed upon was first to find the nature of the colon-contents in order to fix the diagnosis. An enema of simple warm water was to be given; if this brought away characteristic passages, then high injections were to be given to undo the obstruction, if possible. In case of failure of the latter there remained only abdominal section. Another hour had not elapsed before the telephone rang, and Dr. Neff announced that he had scarcely begun giving the enema when blood freely escaped from the rectum. For diagnosis nothing further was required. In two hours the patient was in the operating-theater of the Presbyterian Hospital. Present: Drs. McCosh, officiating surgeon; Briddon, Thornley, Hawkes, Northrup; the family physician, Dr. Neff, Dr. O'Dwyer, and other guests.

Gentle irrigation brought away free blood. High injection was practised with water at a temperature of 110° F. and a pressure of five feet; a soft catheter was passed three to five inches within the sphincter, no effort being made to pass it further. The hips were elevated, and the buttocks compressed about the rectal tube. No anesthetic was required; the baby continued drowsy, relaxed, pale, and seemingly already anesthetic. As the water slowly crept from the splenic flexure toward the sausage-shaped tumor, accumulating behind the constriction, it formed a tumor to the right of the median line—a tumor easily felt and seen. This tumor, while under observation, the pressure continuing, traveled slowly to the right, and under the hand seemed all at once, with a gurgle, to flatten out and disappear. The condition of the child remained unchanged. No further evidence of tumor being present, the child was returned to the medical ward for further observation.

On examination at nine o'clock the same evening, after the water had been absorbed and the abdomen had become collapsed, there seemed to be a tumor, smaller, in the same location. It was believed that the intussusception either had not been entirely reduced in the first place, the presence of so much water having obscured the condition, or that the intussusception had returned. At 10.30 P.M., eight and one-half hours after the first injection, the child was allowed to nurse. About this time blood and mucus appeared in two passages.

On the morning of the next day the baby was again nursed; it immediately vomited. At 11.45 A.M. it passed bloody mucus, and more mucus passed during the afternoon. Condition remained the same; child mentally a little brighter. Evidences of tumor were doubtful. There was a suggestion of tumor to the feel; if a tumor, it was not as it originally presented itself. The child nursed every three hours. During this day the temperature was 99½–100° F. rectal; pulse most of the time, 124–128.

On the second day in the hospital, the general condition was less favorable; abdomen was rigid. The child was somewhat disturbed, and stupor, relaxation, and pallor were more marked; temperature reached 103° F.; pulse, 142. This was forty-eight hours from the first appearance of symptoms. Indications for prompt relief were pronounced. Dr. McCosh supervising, injections were administered as before, under continuous, prolonged, gentle pressure. Again a cutting operation was meditated if injection did not promptly relieve. The condition of the child at this moment brought out the opinion from some present that injections were unsafe, and that abdominal section offered better promise. The medical men present favored the view of Dr. McCosh, that injections, conducted with the cautions observed in the former attempt at reduction, were justifiable and preferable.

The second injection left the abdomen as before, full of water, with no definite evidence of the condition of the intussusception. The pressure was rather less than five feet, and was held rather longer than the first; till, in fact, the entire abdomen was apparently filled. The child was now allowed absolute quiet for six hours. At the expiration of this time the surgeons and physicians were again to meet and consider the necessity of an immediate abdominal section—in case the second injection failed.

At the appointed hour the meeting took place in the operating-room. So little confidence had we in the second injection undoing the tight obstruction after the failure of the first, that we did not go to the medical ward, but sent for the nurse and child. The nurse appeared, but without the baby, and reported. Her report was embodied in the contents of a napkin—a movement from the bowels containing, beside mucus, much good normal fecal matter—evidence that the intussusception was reduced.

That night the baby slept well and nursed at regular intervals, and in the morning was sent home with its mother, cured. It has remained perfectly well ever since—now six months.

MEDICAL PROGRESS.

Attenuation of Experimental Tuberculosis by the Roentgen Rays.—LORTET and GENOUD (*Lyon Médicale*, 1896, No. 26, p. 305) have recorded a series of observations that go to show that the Röntgen rays are capable of modifying experimental tuberculosis. Eight guinea-pigs in good health and of about the same age were inoculated with bouillon containing a triturate of the spleen of another guinea-pig, manifestly tuberculous. Three were exposed to the Röntgen rays for at least an hour daily for nearly two months, while the remainder were used for control-purposes. In the former the inguinal glands were enlarged, indurated, and circumscribed, while in the latter softening of the glands had taken place, with suppuration and spontaneous evacuation. However incomplete the experiment, it seems to justify the exposure of tuberculous processes to the Röntgen rays, and for purposes of observation some form of superficial tuberculosis would seem most appropriate for the experiment.

Successful Total Ovariectomy During Pregnancy.—At a recent meeting of the Académie de Médecine MOUCHET (*Semaine Médicale*, 1896, No. 31, p. 243) reported the case of a young woman from whom both ovaries were removed during the third month of pregnancy. One of the organs was cystic and the other sclerotic. The pregnancy pursued its usual course without interruption, and terminated normally in the birth of a living child. The puerperium also was unattended with complication.

Traumatic Paralysis of the Radial Nerve Relieved by Stretching.—At a recent meeting of the Académie de Médecine MOUCHET (*Semaine Médicale*, 1896, No. 31, p. 243) reported the case of an alcoholic, forty-eight years old, who in consequence of a fall suffered from paralysis of the radial nerve. After the condition had existed for two months, extension of the paralyzed nerve was practised, and on the following day sensibility had returned to the previously anesthetic parts. Gradually motor power also returned to the paralyzed member, and in the course of ten days recovery was complete.

THERAPEUTIC NOTES.

The Treatment of Whooping-cough with Ichthyol.—MAESTRO (*Semaine Médicale*, 1896, No. 38, p. 304) reports the results secured in a small number of cases of whooping-cough heated with ichthyol. The drug was administered in pill-form in progressively increasing doses. According to the age of the patient, from ¼ grain to 3 grains were thus administered daily, the dose being rapidly augmented to 9 or 15 grains in the twenty-four hours. At times with the internal administration was conjoined the use of inhalations of a three-per-cent. solution of ichthyol in glycerin. In the cases thus treated the symptoms rapidly subsided and recovery speedily followed. The drug was well borne, and no bad effects upon the kidneys or the general state were observed.

An Improved Stomach-tube.—SALOMON advocates (*Berl. klin. Wochenschr.*, 1896, p. 693) the use of a stomach-tube, which, besides the customary opening, has nine openings in the sides. The long axes of these are directed away from the tip of the tube, similar to those of a nozzle for vaginal use. The advantage claimed is the more thorough washing of the walls of the stomach by reason of the direct impact of the water.

Further Uses of Formaldehyde.—From Berlin (*Deutsche med. Wochenschr.*, 1896, Nos. 39 and 40) comes the statement by ROSENBERG that he has used formaldehyde in a new solution with gratifying results. The best-known solution so far is a forty-per-cent. watery one, known as formalin. Opperman used a sixty-per-cent. solution in methyl-alcohol, which he called halzin. Rosenberg has experimented with the latter solution in combination with a small quantity of menthol, to do away with its irritating properties. This fluid he called holzinol, and when he allowed it to evaporate slowly from a small apparatus, he obtained a perfect sterilization of the air and all objects in the room without injury. Even food was rendered absolutely free from germs by it. It had a favorable influence upon whooping-cough in all stages. When used in a solution as weak as 1–100,000 it prevents the development of bacteria, and a solution of a strength of 1–75,000 is germicidal.

Formaldehyde was farther given internally in a solution of milk-sugar (called sterisol). Examination of the urine shows that it is taken up by the blood, and is separated from it by the kidneys so slowly that its germicidal action in transit must be considerable.

Iodin Injections in Hydrocephalus.—RANKE (*Jahrb. f. Kinderheilk.*, Bd. 39, S. 359) describes a case of hydrocephalus treated by iodin-injections. The patient was a child ten months old. The left ventricle was punctured, and 320 c.cm. of serum were let out. After this 10 grams of tincture of iodin, diluted with 20 grams of water, were injected into the left lateral ventricle. There was a slight febrile reaction. Within two and a half weeks after the operation a noticeable diminution in the size of the head was observed. About four weeks after the treatment the patient succumbed to a fatal enteritis.

The autopsy revealed an adhesive inflammation of the walls of the ventricle into which the injection was made, with a resulting diminution in the size of its cavity.

Vomiting of Pregnancy Controlled by Orexinum Basicum.—RECH records in the *Centr. f. Gyn.*, 1896, No. 33, an instance of the value of orexinum basicum in the vomiting of pregnancy. The patient, a primipara, aged twenty-three years, vomited so badly from the beginning of pregnancy that by the middle of the fourth month she weighed 88 lbs. instead of 104, and various remedies and nutritive enemata were tried in vain. Rech gave her 5-grain doses of orexinum basicum three times daily for three days. After the third powder the vomiting ceased, and in four days the patient had gained enough strength to leave her bed.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, DECEMBER 12, 1896.

THE CHICAGO DIPLOMA-MILL IN A NEW GUISE.

THE Chicago institution for the sale of medical diplomas, known as the Illinois Health University, to which we recently called attention, being unable to withstand the notoriety given to it, has thrown off the name under which it suffered castigation, and has adopted the more businesslike title of "Independent Medical College." Under this new guise, it essays to show its teeth and claws, and e'en to alarm the timid by the loudness of its roar. It boldly announces in a circular-letter from its president that a Constitutional Liberty League is being organized to protect the worthy purchasers of its diplomas, and to resist all interference on the part of boards of health and licensing boards. But the nature of the beast under this lion's skin is all too apparent by the quality of its voice, as well as the length of its ears, and its threatening tones are readily recognized as the brayings characteristic of its ill-disguised nature. To give volume to its wild rantings, and with the possible hope of projecting its voice to the remotest confines of ignorance and moral indirection, with the assumption of its new title it simultaneously exploits a journal called *The Medical Liberty News*, devoted to the advancement of "the cause." The first number of this new accession to journalism—a penny monstrosity, consisting of two pages of letterpress, each 5 x 9 inches, and two illustrations—is ludicrous to a degree. The venom that lurks within appears in the form of an adroit attack on vaccination, serum-therapy, and animal experimentation, undertaken, no doubt, with the hope of enlisting the sympathies of the antivivisectionists and inducing them to join hands with the Liberty League. It has yet to be proven, however, that possession of an obsession on the part of the antivivisectionists is inimical to mental integrity on every other point, and therein lies the hope that this last effort may prove futile.

It is becoming more and more evident that the rapid change of front by this guerillalike institution is proving too much for the Illinois State Board of Health, as well as the active opposition of our energetic contemporary, the *Journal of the American Medical Association*. We shall be glad to tender our assistance in whatever direction it may prove most effective.

AN UNPAID DEBT WE OWE OUR PROFESSIONAL BROTHERS.

"EVERY age confutes old errors and begets new," says the proverb. We are prone to rail at and pity the self-satisfied ignorance of our predecessors, and naturally imagine our own scientific acquirements solid bone and muscle, never reflecting that some, not remote, successor with his trocar of advanced science will find our boasted brawn to be only wind.

This general pneumatosis with its inevitable cerebral emphysema, blinding us to all except others' faults, is deadly to exact science and real progress Our art is the sum of written and traditional experience. As "he is lifeless that is faultless," some of our experience consists of mistakes and failures. These, when acknowledged, are, however, more instructive than successes; but where are we to turn to find writers publishing, or lecturers telling of, their errors in diagnosis, prognosis, or treatment? There are noteworthy examples, but they are few. Some years since a distinguished Philadelphia physician and surgeon had a series of articles in the MEDICAL NEWS describing his mistakes and failures, and rarely could anything be

found so instructive. Likewise, eight or ten years ago, the *Medical Press and Circular* (Eng.) had a series of letters from a "Professional Failure" which, although half humorous and anonymous, were of great value. Such communications should not be anonymous, but manly confessions of error. If, guided by the teaching or experience of others, we fail of success, is it not our duty, as members of a liberal and benevolent profession, to tell our failures, lest others, unwittingly, make the same mistakes? Experience is the best teacher, but a score of lives should not be sacrificed to demonstrate the worthlessness of some new therapeutic or surgical suggestion.

If experimenters would rush into print with failures as they do with successes, how much delay, alas! too often a fatal delay, in reaching wise conclusions would be saved, as well as unnecessary human suffering? Our medical journals bristle with marvelous cures and brilliant surgery. How seldom does the pathologist get his innings to tell the honest sequel! The majority of cases are reported prematurely. Let us not be so greedy of first laurels which may prove to be foul weeds of error, but, after sufficient time has proven our experience successful or faulty, let us make a clean breast of all and win thereby the admiration and gratitude of others, saved from what has proved to us to be unknown pitfalls.

The good Book says: "He that covereth his sins shall not prosper, but who confesses and forsakes them shall have mercy," and, we might add parenthetically, the respect and confidence of his fellows. The duty thus outlined will require fortitude and a sublime humility, but will bring to the performer of that duty the great reward of an unselfish act—peace of mind.

THE SO-CALLED ACCIDENTAL CUTANEOUS RASHES.

Attention has from time to time been called to the fact that, in many instances, physicians are misled into making a diagnosis of skin diseases by the appearance upon the skin of eruptions which are in reality due to the effect of drugs, but which are thought to be due to the presence of some true skin lesion. So frequently is this mistake made that within the last few months a prominent dermatologist has said that quite a large proportion of the cases of skin lesions which he sees in consultation with other physicians is traceable to the drugs that the patient has been taking for the cure of some other ailment. It is not the intention at this time, however, to call attention to those lesions which are, perhaps, most commonly produced by such drugs as quinin, potassium iodid, and the various derivations of coal-tar that are so popular in medicine at the present time, but rather to speak of the accidental rashes that are sometimes seen upon the skin as early symptoms—aberrant manifestations, or post-eruptive manifestations, of some of the diseases which are characterized by changes in the cuticle. It is a well-known fact that in addition to the characteristic eruptions of the various infectious fevers, we frequently find developed upon the skin other eruptions which are by no means types of those which would naturally be expected to appear. Thus in the early stages of smallpox it is not rare to find that certain portions of the patient's body are covered by an eruption which so distinctly resembles that of measles that it is only by the exercise of extraordinary caution that a false diagnosis is not made; and, under the name of Grisolle's sign, it has been stated that the only way to separate this measleslike eruption of smallpox from the true eruption of measles is by stretching the skin between the fingers, when, if the disease be measles, no papule can be felt under the part that is tense, whereas, if it is smallpox, the papule can be distinctly felt.

Again, it is a noteworthy fact that very frequently there develops after vaccination a roseolous eruption or erythema which misleads the physician into a diagnosis of scarlet fever, or of some mild attack of a dermatitis, and even in typhoid fever the rose-rash may be so widely distributed as to closely resemble that of measles in its general outline. Rarely, too, a similar roseolous rash follows an attack of smallpox, and in many of these instances it has been noted that the fever of sepsis in this disease has been unusually severe.

The writer's attention has been called particularly to this subject, not only by a recent study which he has made of it, but more recently by a very valuable paper in Simeon Snell's *Quarterly Medical Journal*, for October, 1896, in which Meredith Richards records his experience with accidental rashes occurring in the course of exanthemata. The value of his paper can be judged to some extent by the fact that

nearly all the instances of accidental rash which he records have been noted by himself—in nearly 8000 cases of infectious disease which he has had under his care during the last four years, while Medical Officer of Health in Chesterfield. In addition to the scarlatiniform rash preceding smallpox, which we have already noted, he calls attention to the fact that petechiæ may be associated with this rash, and, in addition, in some cases a petechial rash breaks out in the groins and axilla before the general variolous eruptive process. In other instances a general purpura asserts itself, and finally an urticaria-like papular erythema, general in its distribution, is sometimes seen. Because of these accidental rashes sometimes preceding smallpox, Richards emphasizes the importance of delay in reaching a diagnosis, particularly during an epidemic of this disease, and states that he has met with about one dozen cases in which the presence of a scarlatiniform urticaria has led to a diagnosis of scarlet fever, when a careful inspection of the throat, or a few hours' delay, would have shown that the case was really one of smallpox. He also states that in addition to the general erythema following smallpox, which we have mentioned, he has noticed a gyrate form of impetigo contagiosa, in which the smallpox-pustules, instead of drying up on the eleventh day, spread peripherally and presented lesions closely resembling those of the skin-diseases we have named. This eruption is frequently attended by high temperature and other evidences of septicemia, and Richards believes that it is due to a mixed infection, as it has a tendency to occur in particular wards, and may be accidentally acquired by attendants. Richards also points out that even in such mild diseases as varicella or chicken-pox, a diffuse scarlatinous rash may appear, which will gravely mislead the physician; and often in enteric fever the so-called scarlatinous rash will be so like that of measles as to give rise to the diagnosis of measles or typhus.

In regard to scarlet fever, he maintains that a dark red macular erythema, which first appears on the limbs about the extensor surfaces of the joints, may spread to the trunk or to the face, and develop after the disease has been a number of days in existence. It would seem probable from his observations that this skin lesion occurs most frequently in those patients who have severe ulcerating sore throat in addition to the scarlet fever, and when this rash appears, as it usually does, during the third week, he regards it as of grave prognostic import. He believes, however, that the violent septic sore throat will nearly always render a diagnosis easy.

These accidental rashes are, however, not limited merely to the condition which Richards has described. They are seen in connection with many affections of the blood, particularly those associated with sepsis; and the so-called "surgical scarlet fever" is practically, in the vast majority of cases, nothing but a skin manifestation of a septic condition of the blood. In these cases, too, one of the most valuable points in differential diagnosis is the absence of sore throat in the septic cases; for, as we know, in true scarlet fever a sore throat is a very constant symptom, the inflammation being of the character that once seen it is always afterward recognized. Then, too, we must remember that it is possible for persons suffering from what are apparently the early stages of the ordinary eruptive fevers, to be in reality the victims of syphilitic infection in the febrile stage, and because of the early stage of their disease, are covered by a roseolous eruption. In every case in which this occurs, particularly if the patient be an adult, the initial lesion should be sought for before making a diagnosis of one of the ordinary eruptive fevers.

Serious mistakes are so frequently made in the diagnosis of the eruptive diseases of both children and adults by otherwise careful physicians, that too much attention cannot be paid to this subject.

SECONDARY PUERPERAL HEMORRHAGE.

Severe bleeding is sometimes seen sufficiently long after labor to justify the use of the term "secondary" in describing it. It is always a serious matter, and especially so with private patients in whom it occurs after the physician has left the case, supposing that danger of hemorrhage is past. It was one of the themes for discussion at the last meeting of the British Medical Association, where it was considered at length by the leading obstetricians of Great Britain.

Routh, in a paper upon the subject, said that he had found this bleeding "concealed," or "external"; in the former instance, the cervix was closed by a clot which prevented the escape of blood; in the latter, blood flowed freely from the vagina. He had

found sudden relaxation of the uterus, from nervous shock, to be the principal cause. Next in order of frequency was the partial separation of a piece of retained placenta, or sudden loosening of thrombi from the uterine sinuses, by exertion, or by the action of ergot. This was observed in cases where ergot was given before the birth of the child, and where irregular contraction of the uterus and retention of clots followed. Byers had seen a case where distended bladder seemed to be the cause of the bleeding. Donald had seen hemorrhage follow the absorption of retained fecal matter as late as the eighth or ninth day after labor; others had met with this bleeding as late as the end of the first week, accompanying a backward displacement of the uterus.

The writer has observed such cases in young, ill-developed women who were anemic and who had frequently suffered from exhaustion caused by hard work before delivery. Depressing emotion was undoubtedly a powerful factor also in these cases. Malaria has been present in some.

Secondary hemorrhage comes on suddenly with little, if any, warning. Sometimes considerable mental agitation precedes it, but frequently the first intimation which the nurse has is the flow of blood, or the weakened aspect of the patient. If the hemorrhage is not concealed, the flow is copious and bright in many cases; in others, it begins gradually, is dark in color, and persists until syncope results. The uterus is relaxed and soft, sometimes distended with clots, and often displaced backward in the abdomen. If bleeding occurs as late as the end of the first week, the uterus may be found in the hollow of the sacrum. On palpating the abdomen, the hard outline of the organ is lacking, and in severe cases it cannot be felt.

The prevention of such bleeding lies in the thorough study of each pregnant patient. Where such a woman is evidently ill nourished, her blood should be examined, and iron or arsenic, or the peptomanganate of iron should be given as indicated by the blood-count. Where pregnant women become anemic from toxemia, the eliminative organs must be stimulated to act properly. Where insufficient nourishment is the cause of the trouble, proper food must be procured for those who are needy, and the diet of others must be properly regulated. The depressing influences of lack of fresh air, hard work, and exhausting anxiety must be removed as far as possible.

During labor, the obstetrician must keep in mind the danger of uterine relaxation which follows prolonged labor, and which accompanies the improper use of certain uterine stimulants. Should the mechanism of labor be at fault, he must correct this without delay; should an insurmountable obstacle to delivery be present by reason of disproportion between the fetus and the pelvis, he must detect this before exhaustion supervenes. In prolonged labor, the mother's strength must be conserved by proper nourishment and the use of appropriate tonics, anesthetics, and anodynes. Clinical experience proves without doubt that the giving of ergot during labor predisposes to secondary hemorrhage. If uterine contraction is deficient, it is best stimulated by a general tonic such as quinin, or a moderate amount of alcohol, and uterine force is best supplemented by manual pressure, or traction by forceps. Ergot produces excessive muscular contraction ending in relaxation, and strychnia brings about a tetanic condition of the uterine muscle which ultimately terminates in exhaustion. Contrary to what is often stated, sudden emptying of the uterus does not necessarily predispose to bleeding; in Cæsarean delivery, the child is suddenly removed, yet serious bleeding rarely follows unless the patient has been exhausted before the operation.

Haste in expressing the placenta is a common cause of secondary bleeding. So long as the patient does not bleed, the placenta may be left within the uterus from twenty minutes to half an hour with positive advantage. It will gradually become separated and ready for expulsion. Should it be necessary to deliver the placenta, Crédé's method is unquestionably best and safest. Where the hand must be introduced, the placenta should be removed very gradually, and the inner surface of the womb thoroughly examined by touch to be sure that no portion of the after-birth remains.

After labor, when birth has been exhausting and delayed, uterine relaxation and secondary bleeding should be feared, even if the patient does well immediately after labor. Following delivery, the uterus should be well douched with hot sterile water, and moderately tamponed with sterile or antiseptic gauze. The vagina may also be filled with antiseptic gauze, but not to the degree of over-distention. The uterus should be anteverted and, if possible, anteflexed by the hand of the physician, the fundus being carried

above the promontory of the sacrum, and bent strongly forward. It should be retained in this position by the hand of the doctor or nurse until it ceases to relax, and remains well contracted. When such is the case, the abdominal binder, or many-tailed flannel binder, used after abdominal section, should be applied from above downward, making firm pressure upon the uterus. Three towels may be rolled firmly, and one placed above the fundus, and one on each side of the womb beneath the tightly pinned binder; this is more efficient than a simple pad, but if bleeding is feared, the binder should not be applied, but the womb should be watched by the hand of the nurse or doctor. After the womb is empty, strychnia and ergot are indicated in cases where labor has been prolonged. Care should be taken that these remedies are used for the first thirty-six or forty-eight hours after delivery, and not simply in one or two large doses; the better way is to give $\frac{1}{40}$ of a grain of strychnia and 20 drops of ergot every six hours for a day and a half, or two days. Rectal injections of whisky, well diluted with warm water, serve well in these cases. In nervous and frightened women, opium is an important aid in preventing secondary bleeding; in the form of codeia, given by hypodermic injection, it allays fear and anxiety, and thereby prevents nervous exhaustion; in doses of $\frac{1}{4}$ to $\frac{1}{2}$ of a grain, it serves a most useful purpose.

In the presence of secondary hemorrhage, vigorous treatment is demanded. The uterus should be grasped and kneaded, and a douche of hot sterile water promptly given. Upon the physician's arrival, he should at once explore the uterus with the aseptic hand, and remove any large clot or loosened bit of placenta which may be within. An intra-uterine douche of hot sterile water should accompany this manipulation. When the womb is clean and empty, it should be tamponed with aseptic gauze, and carried into proper position, the fundus just above the brim of the pelvis, and directed strongly forward. Strychnia, given by injection, and ergot, by the mouth, will usually complete the treatment. The uterus must be watched by the hand until it is evident that relaxation will not occur. For the anemia which follows severe secondary bleeding, the injection of normal saline solution under the skin is clearly demanded; from a half pint to a pint should be given as soon as possible, and this may be supplemented by injections of warm water and whisky in the rectum, thus securing the rapid absorption of considerable water. The writer recently saw a case in a young anemic girl in which secondary bleeding came on suddenly, twenty hours after delivery, after the patient had dropped asleep; it was promptly checked, only to recur twenty-four hours later. In each instance it yielded promptly to uterine massage and the hot douche, without further treatment; the patient ultimately made a good, although prolonged, recovery from gestation.

Edward P. Davis, M.D.

ECHOES AND NEWS.

Colored Physicians Organize.—The colored physicians of South Carolina have formed a State organization.

Resignation.—Dr. Egbert H. Grandin has resigned the assistant editorship of the *Medico-Surgical Bulletin.*

Spread of the Plague in India.—The bubonic plague is still spreading in Bombay, and is now attacking Europeans, two of whom have died.

A Collection of Brains.—Dr. Luys of the Salpetrière Hospital, Paris, has presented the Faculty of Medicine with his collection of 2200 brains.

Antitoxin in Louisiana.—The Louisiana State Board of Health has announced that it will supply antitoxin free of charge to poor diphtheritic patients.

Starvation in India.—The mortality from famine in the Belapur and Belaghal districts is steadily increasing. Hundreds of persons have died from starvation in the Gonda district.

Dr. Jameson Released from Jail.—On the evening of December 2d, Dr. Jameson was removed from Holloway Jail in an ambulance. He was taken to a private sanitarium in one of the suburbs of London.

Huckleberry-wine.—Wine made from huckleberries is now sold in large quantities in Austria and Germany. It is cheap, and Professor Pettenkofer, a hygienic authority, says it is much better than the average table-wine made of grapes.

A New Hospital Building.—The Morristown, N. J., Memorial Hospital will apply a donation of $38,000 to the erection of a building on its grounds. This, it is hoped, will be the central portion of a larger hospital to be built in three sections.

To Lengthen the German Curriculum.—To stem the overcrowded condition of the profession in Germany, it is proposed to add a sixth year to the medical student's curriculum. This is to be spent in practice in hospitals or specially recognized clinics.

The Responsibilities of Druggists.—The Supreme Court of North Carolina has decided that where a druggist sells

opium to a woman whose husband has warned him not to do so, and the use of the drug affects the woman's health, the druggist is liable for damages.

Resolutions.—The Medical Board and Board of Directors of the Manhattan Eye and Ear Hospital, New York City, have adopted resolutions expressive of their high appreciation of the services of the late Dr. Frank W. Ring, as executive surgeon of the hospital, and sorrow at the loss the institution has sustained in his untimely death.

Mr. Tesla on the X-ray.—Regarding some sensational reports that have found their way into newspapers recently, in which it was stated that blind eyes were made to see through the mysterious agency of the Röntgen-ray, Mr. Tesla very properly considers them groundless. He further deplores the cruelty of raising such vain hopes in the minds of the unfortunate.

State Charities.—The annual meeting of the New York Charities' Aid Association was held December 4th. Stereoptical views of the institutions in the Department of Public Charities of New York were exhibited. The secretary stated that contracts were signed in November for the construction of new buildings in both the Department of Charities and that of Correction. Dr. Frederick Peterson submitted a report on the Craig Colony for Epileptics.

St. Christopher's Hospital for Babies.—The St. Christopher Hospital for Babies was opened in Brooklyn December 1st. No child suffering with a contagious disease can be received, but all others, sick and destitute, will be taken to the full capacity of the hospital. The consulting staff consists of Dr. A. J. C. Skene, Dr. Charles Jewett, Dr. Wm. Madden, Dr. Wm. Browning. The visiting pediatrists are Dr. Wm. A. Northridge and Dr. John W. Parrish.

Hospital Boards Selected.—In pursuance of the recent revision of the lunacy law by the Legislature requiring the reorganization of the Boards of Managers of the several State Hospitals for the Insane, Governor Morton reappointed the then existing boards for the Manhattan and the Long Island State Hospitals, including two women for each board. The Governor appointed new boards for the Hudson River and Utica State Hospitals, following out his policy of having women representatives in each management.

Burns Caused by the X-ray.—A case is reported from Chicago in which the back of the patient was seriously burned in an endeavor to locate a bullet in his back by the X-ray. This is one of many reported cases of burn produced in this way. Such wounds heal more slowly than ordinary burns. Nikola Tesla states that these effects are not due directly to the rays, or Röntgen streams, but to the ozone generated by the rays in contact with the skin. He recommends a coating of oil on the skin as a preventive measure.

Sees His Own Heart Beat.—The report comes from Indiana, that a boy, aged fifteen, while rabbit shooting November 14th, accidentally shot himself in the left breast. Parts of the second and third ribs were carried away, and an opening three inches in diameter was made in the chest wall. Through this the lung and heart were plainly seen. The surgeons in attendance used a silver plate to close the opening, wiring it to his ribs and covering its edges with skin grafts. Before the operation a mirror was placed in position so the boy could see his own heart beat.

New York Police Ambulances.—At their next meeting the Police Commissioners of New York City will consider the suggestion of adding an ambulance to the equipment of every police station. This can only be regarded as an evolution from the service of the present patrol-wagons. The number of police surgeons must be increased accordingly, so that each station shall have one constantly within easy call. The ambulance service rendered by the hospitals is sometimes inadequate to meet the demands, and is often taxed unjustly in the removal of persons not properly requiring their attention.

The Congress of Leprologists.—There will be held at Berlin in October, 1897, a conference of a very limited number of renowned leprologists and delegates of the different governments to discuss the slow but sure increase of leprosy and the measures to oppose this plague. The conference was fixed for the month of March, 1897, but the scientific expedition of Professor Robert Koch to South Africa (for the British government) has necessitated a delay of the date. The members of the organizing committee are Messrs. Armauer Hansen (Bergen in Norway), Robert Koch and O. Lassar (Berlin), and Edward Ehlers (Copenhagen), as secretary.

A Crime Against Humanity.—Judge Gordon of Philadelphia, with the able assistance of Drs. Weir Mitchell, Morton, and Mills, is now conducting an investigation of the practice of unlawfully (?) detaining insane persons in the Eastern Penitentiary of Pennsylvania. It has already developed that there are quite a number of these unfortunate cases, and it is stated publicly by Judge Gordon that there is an element in the administration of this institution which tends to promote insanity among its inmates. He also believes that for certain reasons those in charge are indisposed to give these facts publicity or assist in the removal of these prisoners to more suitable environments. It is disgraceful negligence on the part of any State, especially one maintaining such advanced ideas of statutory justice and philanthropy as does Pennsylvania, to be without separate provisions for the care of insane criminals.

The Courage of President Kruger.—Poultney Bigelow, in *Harper's Monthly*, narrates instances of almost incredible courage on the part of Paul Krüger. The Transvaal President was shooting one day when his gun exploded and blew away part of his left thumb. The surgeon to whom Krüger finally submitted the case, found that the flesh had begun to mortify, and advised amputating the arm at the elbow. Krüger demurred, nor would he permit the alternative suggestion of having the hand cut off. The surgeon refused to deal further with the case. Krüger thereupon laid the thumb upon a stone and cut off a por-

tion of the affected part. The wound still refusing to heal he cut away all the flesh about and above the second joint of the thumb, and this time the flesh healed and his hand was spared. On another occasion when suffering from toothache, he forced the tooth out of his jaw with a penknife.

Lying-in Hospital Society.—The annual report of the Society of the Lying-in Hospital, New York, has just been issued, giving in detail the work for the year ending October 1, 1896. During the past two years 3423 applicants for relief have applied at the hospital and substation, and 2768 of these attended in confinement, an increase of fourty-four per cent. over the corresponding period a year ago. The society cares for the great bulk of its patients in their own homes, removing to the hospital building only cases requiring the most careful watching and treatment. In relief and treatment of those who applied for aid, scattered throughout the tenement districts in the lower part of the city, more than 37,800 visits were required. During the year 341 students have received certificates. Nurses from St. Vincent's Hospital in this city, St. Joseph's in Yonkers, and St. Mary's in Brooklyn, to the number of fifty-five, have been carefully trained.

Examples of Longevity.—The London *Standard* remarks that longevity, like the dew of heaven, comes to every class. Kings who live in luxury, beggars who go through existence in a state of chronic cold and hunger, giants and cripples, abstainers and drunkards, large eaters and small eaters, toilers and sluggards, brain-workers and body-workers, vegetarians and carnivora, smokers and non-smokers, sane and insane—all have apparently an equal chance of the prize of long life. Among a host of others one gentleman of 127 years, a grandson of the famous Thomas Parr, attributes his length of days to extreme temperance and regular exercise. And Mrs. Judith Bannister, who died at Cowes in her 108th year, lived on apples, biscuit, and milk and water for the last sixty years of her life; while a man named Confit of Burythorpe achieved the wonderful span of a century and a half through moderate eating, great exercise, and gulping down a raw egg once a day. An Earl of Huntingdon contrived to celebrate one hundred birthdays. He took care to eat oysters at every meal. Roasted turnip for supper every night in the year formed the elixir that carried Mr. Wilson of Sussex through 116 years. And Mr. Elkins of Combe lived a century by feeding, during the latter two-fifths of it, on bread, milk, and turnip-tops. Mrs. McCarthy of Cork breakfasted at seven, dined at one, and supped at half-past six. This she declared was the secret of her long life. She died aged 103 years. But Philip Laroque, a Gascony butcher, was drunk twice every week for eighty years, and yet lived to be 102, while a Kerry man, named McCarthy, drank rum and whisky as we take tea and coffee. If he was ever tempted to descend to claret or ale, he drank, immediately afterward, an equal quantity of poteen, "as a wedge," he said. He kept doing this for 111 years. Smoking heavily was the practice that kept Mrs. Robinson, a Scotch woman, going for 106 years. May it be that those who attain longevity do so not through adherence to hygienic principles, but through a mystic property of the blood-serum?

SPECIAL ARTICLE.

THE USE OF ANTITOXIC SERUM IN THE TREATMENT OF DIPHTHERIA UNDER THE SUPERVISION OF THE NEW YORK CITY HEALTH DEPARTMENT, WITH A RESUME OF THE PUBLISHED REPORTS ON THIS SUBJECT.

By HERMANN M. BIGGS, M.D.,
OF NEW YORK;
PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES, NEW YORK HEALTH DEPARTMENT,
AND
ARTHUR R. GUERARD, M.D.,
OF NEW YORK;
ASSISTANT BACTERIOLOGIST.

ON January 1, 1895, the New York City Health Department commenced the use of the diphtheria antitoxin prepared in the bacteriological laboratories. For about six weeks after this date, however, the serum at command was limited in amount and was not of a satisfactory strength. The supply of foreign preparations of antitoxin at this time was very small; only a few vials could be obtained under any conditions, and the prices charged were exorbitant, averaging about 80 cents per 100 antitoxin units (Behring's standard), or from $8 to $12 a dose. The price of similar preparations now, as furnished by the Health Department, is from 75 cents to $1.50, or 10 cents per 100 units.

The serum prepared in the laboratories of the Health Department was first employed in the hospitals, but as soon as a sufficient quantity was at hand, arrangements were made for its administration without charge, on the request of the attending physician, by inspectors detailed for this purpose, in any case of diphtheria occurring in the city. During the period ending October 1, 1896, 1352 cases regarded as diphtheria were treated in their homes by inspectors of the department at the request of the attending physicians, and 1207 persons (excluding inmates of public institutions), who had been exposed to diphtheria, were immunized by the administration of antitoxin. Altogether, more than 3000 injections of antitoxin have been administered and about 6000 visits made. This duty has been mainly performed by Medical Inspectors Drs. H. F. Koester, W. E. Studdiford, J. S. Ennis, L. K. Graves and W. J. Pulley.

The cases referred to above do not include any of those treated in the various institutions of the city, and were, as a rule, among the very poorest classes in the tenement-house districts. They have, generally speaking, been in the most unfavorable surroundings; have been severe cases, or regarded by the physicians in attendance as hopeless cases, and have usually come under observation rather late in the course of the disease. In some of the later cases, however, the reverse of this may be said,

TABLE I.—CASES OF DIPHTHERIA TREATED WITH ANTITOXIN BY THE HEALTH DEPARTMENT, JANUARY 1, 1895, TO OCTOBER 1, 1896.

Total cases of true Diphtheria injected with Antitoxin by the Medical Inspectors of the Health Department, showing the number of cases injected, and the mortality percentage, prognosis at time of injection, extent of membrane in the throat, complications, and number of injections given:

	Cases.	Deaths.	Mortality, per cent.	Prognosis.			Extent of Membrane.				Complications.[3]				Number of Injections Given.					Total Injections Given.	Number of Antitoxin Units Injected.
				Good.	Fair.	Bad.	Tonsils	and Pharynx	and Nose.[1]	Larynx.[2]	Broncho-pneumonia.	Nephritis.	Sepsis.	Paralysis.	1	2	3	4	5		
January 1, 1895, to April 1, 1896.....	856	154	17.9	148	261	447	170	280	145	261	8	35	136	7	559	230	60	8	0	1231	600 to 2500

There remain....	1172	118	10.	....	....	....	....	....	....	....	..	..	....	..	....	....	..	..	..	....	.....

NOTES TO TABLE I.—From January 1, 1895, to April 1, 1896, there were treated 856 cases, with 154 deaths, giving a mortality of 17.9 per cent. Of these 65 were moribund at the time or died within twenty-four hours after injection; deducting these, the mortality was 11.2 per cent. From April 1 to October 1, 1896, there were treated 396 cases, with 44 deaths, or a mortality of 11.1 per cent. Of these 15 were moribund, or died within twenty-four hours after injection, and deducting these, the mortality for the last six months was 7.6 per cent. The total mortality from January 1, 1895, to October 1, 1896 (1252 cases and 198 deaths), was 15.8 per cent.; deducting the moribund, it was 10 per cent.

[1] In the nasal cases the pharynx and tonsils were also involved, as a rule.

[2] The larynx involved, with or without the pharynx and nose.

[3] Only the common and more important complications of diphtheria are noted here, and these notes are incomplete. Many other complications occurred (notably scarlet fever), and acted as contributory or determining causes of death. These fatal cases are all included.

TABLE II.—CASES OF LARYNGEAL DIPHTHERIA TREATED WITH ANTITOXIN BY THE HEALTH DEPARTMENT, JANUARY 1, 1895, TO OCTOBER 1, 1896.

Total cases of Laryngeal Diphtheria injected with Antitoxin by the Medical Inspectors of the Health Department, showing the number of cases injected, and the cases, deaths, and mortality percentage in both operative and non-operative cases:

	Total Laryngeal Cases.			Non-operative Cases.			Operative Cases (Intubation).

There remain.....	317	70	22.	249	45	17.9	68	25	36.7

NOTES ON TABLE II.—From January 1, 1895, to April 1, 1896, there were 261 laryngeal cases injected, resulting in 87 deaths, or a mortality of 33.3 per cent. Of these, 25 were moribund at the time, or died within twenty-four hours after injection, and deducting these, the mortality was 26.2 per cent. Of the 64 cases intubated, resulting in 20 deaths, or a mortality of 45.3 per cent., 4 were moribund at the time; deducting these, the mortality of operated cases was 41.6 per cent.; 197 cases, resulting in 58 deaths, were not operated upon, and of these the mortality was 29.4 per cent.; deducting 21 moribund at the time, or dying within twenty-four hours after injection, the mortality for non-operative cases was 21 per cent. From April 1 to October 1, 1896, there were 94 laryngeal cases injected, resulting in 21 deaths, or a mortality of 22.2 per cent.; of these, 13 were moribund, or died within twenty-four hours after injection, deducting which would give a mortality of 11.1 per cent. Of the 8 cases intubated, none died. There were 86 cases not operated on, resulting in 21 deaths, or a mortality of 25.5 per cent.; deducting the 13 moribund cases, or those dying within twenty-four hours, the mortality was only 9.8 per cent. According to the reports of the inspectors, many more of the laryngeal cases might have been saved by earlier treatment and intubation. The total mortality of laryngeal cases from January 1, 1895, to October 1, 1896 (355 cases and 108 deaths), was 30.4 per cent.; deducting the moribund, it was 22 per cent.

as physicians who had seen the effects of antitoxin on the course of diphtheria, and had thus been convinced of its value, not infrequently referred comparatively mild cases for treatment at an early period of the disease. It will be noted by reference to the accompanying tables that, during the first year of this work, up to April 1, 1896, about eight per cent. of the cases treated were moribund when first seen by the inspectors, while in the last six months the percentage has been reduced to about one-half of this number. In a large proportion of the whole number there was practically no other treatment beside the administration of antitoxin. In some cases strychnia, whisky, and other remedies were also given. In many instances the physician in attendance discontinued his visits, after referring the case to the Health Department for the administration of antitoxin, as the family was unable to pay for his attendance.

There has been from the beginning a continuous and marked improvement in the results obtained, in consequence, it is believed, of increased experience in the use of this agent, the earlier application of the treatment, the constant improvement in the character of the serum, and the larger dosage employed. During the first year (see table No. 1) the mortality was seventeen and nine-tenths per cent., while during the last six months the mortality was only eleven and one-tenth per cent.

For the execution of the plan adopted for the free administration of antitoxin among the poor the city was divided into districts, each district being placed in the charge of an inspector, who is always on duty and liable to call at any hour during the day or night. The requests for the administration of antitoxin are received at the offices of the Health Department, and immediately referred by police telegram, or by telephone, to the inspector in charge of the district in which the case occurs. In some instances during the last months, where several cases have been treated by the same physician, they have been referred by him directly to the inspector, in order that valuable time might thus be saved.

There were treated up to October 1st, all included, 1352 cases regarded as diphtheria. Of these 100 cases showed later on bacteriological examination no Loeffler bacilli—were considered as false diphtheria and excluded from the statistics; or were found to be true diphtheria, were later transferred to the Willard Parker Hospital, and thus passed from observation of the inspector; or the treatment was discontinued from some other cause. There remain 1252 cases, of which 1054 recovered, and 198 died, the mortality being $15\frac{8}{10}$ per cent. Of the whole number, 856 were treated previous to April 1, 1896, and among these the mortality was $17\frac{9}{10}$ per cent. Three hundred and ninety-six were treated during the period between April 1st and October 1st, and among these the mortality was $11\frac{1}{10}$ per cent. While the difference in the results may be in part due to the season of the year, yet this does not satisfactorily account for the whole difference in mortality, as reference to the monthly mortality curve of the whole city will show that there was not a corresponding reduction in the general mortality during the latter months.

Of the 1252 cases, 80 were moribund at the time of the first injection, or died within twenty-four hours after it. These may be properly excluded in a consideration of the utility of antitoxic serum in the treatment of diphtheria. There remain 1172 cases with 118 deaths, or a mortality of ten per cent. Five hundred and seventy-four, or nearly one-half of the whole number, were reported by the inspectors to be in a bad condition and suffering from very severe or septic diphtheria at the time of the first injection, and 268, or about twenty-one per cent., were reported as in good condition, or as apparently affected with a mild form of the disease, when first seen. In 355, or more than twenty-eight per cent. of the whole number, the larynx, with or without the pharynx, tonsils, and nares, was involved. In 242 cases, in addition to the pharynx and tonsils, the nares were involved. One hundred and eight deaths occurred among the 355 laryngeal cases, giving a mortality of $30\frac{4}{10}$ per cent. Seventy-two of the laryngeal cases were intubated, in some instances by the inspectors, and in some by the attending physicians, and of these 29 died, or $40\frac{2}{10}$ per cent. In 283 laryngeal cases there was no operative interference and in these the mortality was $27\frac{9}{10}$ per cent. Of the fatal laryngeal cases, 38 were moribund at the time of the first injection or died within twenty-four hours after it. If these be excluded, there remain 317 cases with 70 deaths, or a mortality of twenty-two per cent. Other data as to the mortality in operative and non-operative cases, and as to results in relation to the age of the patient, and the day of the disease on which treatment was begun, are shown in detail in the accompanying tables. (Tables Nos. 1, 2, and 3.)

In a large majority of all cases treated—*i.e.*, 793—only one injection of antitoxin was administered; in 352 two injections were made, and in 108 three or more. In all severe cases the initial dose was large, varying from 1500 to 3500 units, experience showing that the best results were obtained from large initial doses, and the tendency has been to constantly increase the size of this dose. This experience is in direct confirmation of the conclusions reached in the experimental investigations on animals. As a rule, the patients were seen the second time at the end of twenty-four hours, and where it was considered necessary a second injection was then administered. They were afterward seen at intervals until the disease had terminated either in complete convalesence or death.

The serum employed has been generally of high grade, and during the last nine months has been at least twice as potent as Behring's No. 3; that is, it contained 300 or more antitoxin units in each cubic centimeter. During the past three months the serum employed contained from 400 to 500 units in each c.cm. Better results have been obtained with the high-grade preparations, and with larger doses. In the earlier months, where large quantities of serum were administered (the serum containing proportionately less antitoxin), rashes were of frequent occurrence; but no reliable data as to the percentage of cases in which they appeared can be obtained. There has been a considerable diminution in the frequency with which rashes have occurred, and in the severity of these, since the use of the

TABLE III.—CASES OF DIPHTHERIA TREATED BY THE HEALTH DEPARTMENT, ARRANGED ACCORDING TO AGE AND DAY OF DISEASE WHEN INJECTED, JANUARY 1, 1895, TO OCTOBER 1, 1896.

NOTES TO TABLE III.—The total mortality of those injected within the first forty-eight hours of the disease was 8.2 per cent.; deducting the moribund, or those dying within twenty-four hours after injection—4.3 per cent. The mortality of those injected before the fifth day of disease was 12.4 per cent.; deducting the moribund, 7.6 per cent. During the last six months, April to October, there were injected within the first forty-eight hours of disease, 178 cases, with 8 deaths, a mortality of 4.5 per cent.; deducting the moribund, 1.6 per cent. Before the fifth day of disease there were injected 317 cases, with 22 deaths, a mortality of 6.9 per cent.; deducting the moribund, 3.6 per cent.

TABLE IV.—IMMUNIZATION WITH ANTITOXIN BY THE HEALTH DEPARTMENT INSPECTORS, JANUARY 1, 1895, TO OCTOBER 1, 1896.

Table of cases immunized with injections of antitoxin in families where diphtheria had occurred, showing the number of cases immunized, the number of antitoxin units injected, the number of cases of diphtheria which occurred within thirty days after injection, the number of cases which occurred after thirty days and within twenty-four hours after injection, and the number of cases of diphtheria which occurred in the families previous to immunization:

Number of Cases Immunized.	Number of Antitoxin Units injected.	Number of Cases of Diphtheria within 30 days after injection.	Number of Cases of Diphtheria within 24 hours and after 30 days after injection.	Number of Cases of Diphtheria which occurred in families, etc., previous to immunization.
1207	50 to 500	1 on the 7th day.[1] 1 " 10th day. 5 " 19th and 20th days. 1 " 23d day. 1 " 30th day. } Mild. 1 severe on the 5th day recovered. 1 on the 2d day died of scarlet and diphtheria.	After 30 days. 2 mild recovered.[2] 1 on 55th day died. Within 24 hours. 7 mild pharyngeal. 5 croup, all recovered.	One or more cases in 395 families.

[1] Probably had nasal diphtheria at the time of immunization.

[2] The data as to cases occurring after thirty days have but little value, as cases might have appeared without the knowledge of the Health Department.

There remain	354	47	13.2	...	..	..	...	...	..	..	..	...

NOTES TO TABLE V.—From October 1, 1895, to April 1, 1896, there were treated with free antitoxin 86 cases, resulting in 15 deaths, or a mortality of 17.2 per cent. Of these 3 were moribund at the time of injection, or died within twenty-four hours after the first injection, deducting which would give a mortality of 14.4 per cent. In 60 cases the diagnosis was bacteriologically confirmed, and of these 6 died, or 10 per cent.; 56 cases were clinically diagnosed, of which 9 died, or 37.5 per cent. From April 1, 1896, to October 1, 1896, there were treated 289 cases resulting in 53 deaths, or a mortality of 18.3 per cent. Of these, 18 were moribund at the time of injection, or died within twenty-four hours after the first injection, deducting which would give a mortality of 12.9 per cent. In 241 cases the diagnosis was bacteriologically confirmed (in 24 cases the examination was indecisive), and of these 35 died, or 14.5 per cent.; 48 cases were clinically diagnosed, and of these 18 died, or 37.4 per cent. Of the 289 cases treated, 60 occurred in institutions, with 9 deaths, or 15 per cent. mortality.

Of the entire number of cases reported, 34 cases are excluded from the statistics on account of imperfect data in the reports, or no Klebs-Loeffler bacilli being found, or the cases being removed to the Willard Parker Hospital and treatment discontinued. In a total of 375 cases treated by physicians with free antitoxin from October 1, 1895, to October 1, 1896, there were 68 deaths, or a mortality of 18.1 per cent.; deducting 21 cases which were moribund at the time, or died within twenty-four hours after the first injection, there were 354 cases, with 47 deaths, or a mortality of 13.2 per cent.[1] Of the total number treated, in 100 cases the tonsils alone were involved; in 90 cases, the pharynx alone, or tonsils and pharynx; in 58 cases, the nose alone, or nose, pharynx, and tonsils; in 127 cases the larynx was involved, either alone or in combination with tonsils, pharynx, and nose. In this table the *prognosis* at the time of treatment, and the *complications* accompanying or following the injections, are not included, because the data given in the reports were insufficient or incomplete.

TABLE VI.—LARYNGEAL CASES TREATED BY PHYSICIANS WITH FREE ANTITOXIN, OCTOBER 1, 1895, TO OCTOBER 1, 1896.

	Total Laryngeal Cases.			Non-operative Cases.			Operative Cases (Intubation).

There remain	116	26	22.4	79	17	21.5	37	9	24.3

NOTES TO TABLE VI.—From October 1, 1895, to April 1, 1896, there were 33 laryngeal cases treated with free antitoxin, resulting in 12 deaths, or a mortality of 36.3 per cent.; 23 cases were not operated on, with 7 deaths, or a mortality of 30.4 per cent.; 10 cases were intubated, resulting in 5 deaths, or a mortality of 50 per cent.

From April 1, 1896, to October 1, 1896, there were 94 laryngeal cases treated with free antitoxin, resulting in 25 deaths, or a mortality of 26.6 per cent. Of these, 10 were moribund at the time, or died within twenty-four hours, deducting which, the mortality would be 17.8 per cent.; 62 cases were not operated on, with 16 deaths, or a mortality of 25.8 per cent.; of these, 6 were moribund at the time, or died within twenty-four hours, deducting which would reduce the mortality to 17.1 per cent.; 32 cases were intubated, with 9 deaths, or a mortality of 28.1 per cent.; of these, 4 were moribund, or died within twenty-four hours, deducting which would reduce this mortality to 17.8 per cent. In a total of 127 laryngeal cases treated by physicians with free antitoxin from October 1, 1895, to October 1, 1896, there were 37 deaths, or a mortality of 29.1 per cent.; of these, 11 were moribund at the time of injection, or died within twenty-four hours after the first injection, and if these be deducted, there remain 116 cases, with 26 deaths, or a mortality of 22.4 per cent.; 85 cases were not operated on, of which 23 died, a mortality of 27 per cent.; deducting 6 moribund, or dying within the first twenty-four hours, there remain 79 cases, with 17 deaths, or a mortality of 21.5 per cent.; 42 cases were operated on, with 14 deaths, a mortality of 33.3 per cent.; deducting 5 moribund, or dying within the first twenty-four hours, there remain 37 cases, with 9 deaths, or a mortality of 24.3 per cent.

higher grade preparations of antitoxin in which smaller doses of serum are employed. Joint symptoms were of very unusual occurrence. In five instances abscesses followed the administration of the serum; but in none of these could the abscess be properly charged to the serum itself. In two or three of the early cases where large immunizing injections were employed, severe joint symptoms, accompanied by prostration and pyrexia, occurred, and in a number, temporary (twenty-four to seventy-two hours) albuminuria appeared. Aside from the symptoms referred to, and occasionally a temporary pyrexia, no disagreeable effects in any way attributable to the antitoxin were observed. No case has come under observation where death could be ascribed to the administration of the serum, or where any permanent injury could be properly regarded as having been produced by it.

The data as regards complications are very incomplete, as in the class of patients treated and under the conditions existing, careful observations could not be made. Only the more common complications of diphtheria are noted; in many instances other serious complications existed (notably scarlet fever), and acted as contributing or determining causes of death in fatal cases. All such cases have been included.

In all of the cases, with rare exceptions, in which the clinical features were unmistakable, the clinical diagnosis was confirmed by bacteriological examination. In a few cases the result of the bacteriological examination was indecisive, while the case was evidently diphtheria, and these have been included. In others bacteriological examination showed clearly that the case was false diphtheria, and such cases have been excluded from the list. The usual practice has been when a case was seen for the first time by the inspector (at the request of the attending physician) to administer an injection of antitoxin, if it seemed clinically to be a case of diphtheria, and at the

NOTES TO TABLE VII.—From October 1, 1895, to April 1, 1896, there were treated within the first four days of disease 61 cases, with 6 deaths, or a mortality of 10 per cent.; of these 3 were moribund, or died within 24 hours, deducting which the mortality would be 5.1 per cent. From April 1, 1896, to October 1, 1896, there were treated within the first four days of disease 215 cases, with 32 deaths, or a mortality of 14.8 per cent.; of these, 11 were moribund, or died within twenty-four hours, deducting which the mortality would be 10.2 per cent. In a total of 276 cases treated within the first four days of disease, there were 38 deaths, or a mortality of 13.7 per cent.; deducting the 14 moribund, or dying within the first twenty-four hours, the mortality would be 9.1 per cent. In a total of 138 cases treated within the first three years of life, 39 died, or a mortality of 28.2 per cent. From the third to the tenth year there were 212 cases treated, with 28 deaths, a mortality of 13.2 per cent. From the tenth to the fifteenth year the mortality was 7.1 per cent. Over fifteen years, none died. Two-thirds of the cases treated were under ten years of age.

same time to make a culture from the throat for bacteriological examination, if a culture had not been previously made. The course subsequently pursued in each case depended upon the results of the bacteriological examination.

When cases of diphtheria were seen in families in which there were other children, who had been exposed to the disease, and when the parents would allow it, an immunizing injection was administered to each of them, and trial cultures were made from their throats. In a large percentage of these cases, the cultures showed the presence of Loeffler bacilli.

Immunizing injections, varying from fifty to 500 units in amount, were administered to 1207 persons (see table No. 4). In five children who had been immunized, laryngeal diphtheria (croup) developed within twenty-four hours of the time of the injection, and in seven other pharyngeal diphtheria appeared. All of these cases received further curative injections and promptly recovered. In nine cases diphtheria developed within thirty days of the time of immunization. All of these cases excepting two were mild and promptly recovered. In one of these two exceptions, scarlet fever, apparently accompanied by diphtheria, developed on the second day, and the child died.

No data of value are at command regarding the occurrence of cases of diphtheria among those immunized after thirty days; but in one instance it is known that a child developed diphtheria on the fifty-fifth day after immunization, and although it received a curative injection, it nevertheless died from the disease. The experience obtained from the immunization of children in various institutions indicates that the protective influence of the immunizing injections cannot be depended upon to last longer than about four weeks, although in many cases the period is apparently longer. With the high-grade preparations of antitoxin now employed, the amount of serum required for an immunizing injection is very small, varying from 3 to 10 or 15 minims, according to the age of the patient and the strength of the preparation. In the earlier work, when young and feeble infants were immunized, some restlessness, accompanied by more or less pyrexia, occurred in many cases during the first twenty-four hours, and not infrequently a rash appeared later. Similar symptoms appeared in a smaller proportion of instances in adults. In a few cases transient albuminuria occurred. Since the employment of only very small doses of serum, it has been unusual to see any disturbances following the administration of an immunizing injection. In one group of about forty cases recently immunized with small doses, in only one instance was there a local rash near the seat of the injection. In another series of 130 cases, immunized in an infant asylum,[1] in which relatively large doses were administered to infants varying in age from one day up, in only seven cases was there a mild body-rash, and in forty-two a local arm-rash, and in no instances were there other sequelæ.

On October 1, 1895, arrangements were made to enable physicians to obtain supplies of antitoxin, free, for use among patients too poor to pay for the remedy, on condition that reports of the cases thus treated should be furnished to the Health Department. Druggists, acting as agents for the sale of antitoxin, were instructed to furnish the remedy free to any physician, upon his statement that the patient for whom it was intended was not in circumstances to pay for it. A blank was furnished upon which the history of the case could be filled out by the attending physician, upon the termination of the case, either by death or complete recovery, and then forwarded to the Health Department.

This arrangement has not been very generally known, and has not been largely utilized by physicians until quite recently, and in many of the cases thus treated the complete report has not been obtained. Up to October 1, 1896, 409 cases of this sort have been reported, of which 34 proved on bacteriological examination to be cases of false diphtheria, were transferred to Willard Parker Hospital, or had histories too incomplete for proper tabulation, and are, therefore, excluded; of the remaining 375, 307 recovered and 68 died, a mortality of $18\frac{1}{10}$ per cent.

The fuller data regarding these cases, as furnished by the attending physicians, will be found in the accompanying tables. (Nos. 5, 6, and 7.)

(To be continued.)

[1] Among injections made at this asylum were cases: No. 117, an infant, three weeks old, born at full term, injected with 150 units, and weighing at the time of injection only four pounds three ounces; and No. 123, a premature infant, nineteen days old, born at seventh month, and still in an incubator, injected with 150 units, and weighing at the time of injection only three pounds eight ounces. These infants had no reaction whatever and no rash.

Among the pregnant women:

Ten were eight months in pregnancy.

REVIEWS.

PRACTICAL DIAGNOSIS: THE USE OF SYMPTOMS IN THE DIAGNOSIS OF DISEASE. By HOBART AMORY HARE, M.D., Professor of Therapeutics in Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital, etc. 565 pages. Illustrated with 191 engravings and 13 colored plates. Lea Brothers & Co., Philadelphia and New York. 1896.

THE object of this volume, the author tells us, is to place before the physician and student the subject of physical diagnosis as it is at the bedside. To accomplish this, the symptoms used in diagnosis are discussed first, and then their application to determine the character of the disease. This plan has the great advantage that the physician, finding himself in the presence of certain symptoms, or groups of symptoms, is, if he follows this textbook as a guide, led to suspect the organ or system involved. So far we are in accord with the author. We cannot agree, however, that the discovery of any marked symptom will lead to the diagnosis. In support of our contention, let us suppose that the physician elicits in a patient the striking symptom—ankle-clonus. From that symptom he may be led to suspect that the patient has disseminated sclerosis, chronic transverse myelitis,

hereditary cerebellar ataxia, or even grave traumatic neurosis, but the elicitation of this one symptom, as an individual symptom, leads him no further than this, and really he must have in mind, or he must learn from books the symptoms necessary to affirm the presence of one and deny all the others of these diseases before he can make the diagnosis. We do not deny the great advantage of the plan utilized by Hare, but we are unwilling to concede all that he claims for it.

The subject-matter is considered in two parts: the manifestation of disease in organs, and the manifestation of disease by symptoms. In the first part, the various natural divisions of the body, such as the face and head, the hands and arms, the feet and legs, the tongue, mouth, and pharnyx, the thorax and the viscera, the skin, eye, blood, etc., are taken up in separate chapters. The chapters on the tongue, mouth, and pharynx, the abdomen and the abdominal viscera, and the blood, in Part I, are masterfully done. The ones that have most disappointed us are those on headache, convulsions, or general spasms, and pain, in Part II, although these chapters contain some ideas that are new and much that modifies previous points of view.

The illustrations, consisting in part of colored plates, in the chapter on the tongue, mouth, and pharnyx, are among the best we have seen. At the present day the author who teaches that "Hutchinson teeth" are a fairly sure indication of syphilis, must experience a sense of loneliness, for, if we construe the signs of the times aright, "Hutchinson teeth" are indeed no more than a manifestation of chronic malnutrition of which syphilis is sometimes a cause, during the formative and early life of the child. We miss in this chapter some reference to accumulations on the teeth and gums, such as the blue line, a manifestation of lead-poisoning to which some importance can be attached.

The chapter on headache we are sure could be made more valuable by the addition of one or two diagrams, showing the usual location of the various forms of pain referred to the head.

In the chapter on convulsions and general spasms the author says: "There can be no doubt that syphilis produces an enormous amount of epilepsy. . . . Indeed, it would be difficult to name any one statement in medicine which receives more widespread assent on all sides than does this." From this statement we courteously, deliberately, and emphatically dissent. There is a form of epilepsy that deserves the name of syphilitic epilepsy, but compared to all the other forms of epilepsy, in point of frequency of occurrence, it is as the number of red men to the number of white men in this country to-day. As proof of the truth of our remarks we refer to articles on the treatment of epilepsy by any recognized authorities to-day, where a comparison may be made of the space allotted to the respective uses of antiluetic medicaments and bromids. Epilepsy, in the vast majority of cases, shows itself before the end of the second decade of life, and of these cases syphilis is the rarest of all causes. It is only in cases of epilepsy occurring after maturity that a history of syphilis is sought for.

The illustrations of the book are numerous, very well done, and exceedingly instructive. It would be less puzzling to students to have a certain conformity of such illustrations as cross-sections of the spinal cord, so that the ventral horns should always be toward the top of the page, or *vice versa*, and not up in one place and down in another, as on pp. 122 and 223. In the chapter on cough and expectoration, an illustration of the coccus of pneumonia might profitably be added.

If we have found something to criticize in this volume, it is because the reputation of its brilliant young author has prompted us to a careful and minute examination of his latest production. Candor compels us to admit that we have found unmistakable evidence of haste in the preparation of the work, and, likewise, what we believe to be unnecessarily frequent drafts on the labors of others. On the other hand, when we say that there is a wealth of information in the volume of the safest and most orthodox kind, and that it is put before the reader in an easily intelligible and convincing way, we desire not to be understood as endeavoring to make amends for faults that we have found with it. On the contrary, we unhesitatingly commend the book to those for whom it is intended, confident that they will receive as much profit in studying it as we have had pleasure in reading it.

THE MEDICAL NEWS VISITING LIST, 1897. Thirty patients per week. Philadelphia: Lea Brothers & Co., 1896.

THIS practical visiting list is now ready. It appears in its usual good form, and presents in as condensed a space as possible the most important data necessary to assist physicians in cases of emergency. In addition, its chief object is not lost sight of, for this little pocket-book affords more than ample means of recording all the daily engagements of the physician, as well as future ones which he proposes to make.

It is in most convenient form, not bulky, and is truly a "pocket-book." It certainly excels in this and in many other respects most of the visiting lists put on the market.

Obituary.—Dr. John A. Arnold, medical superintendent of the Kings County Hospital, died on the 4th inst. Dr. Arnold was fifty-one years of age, and had been connected with the hospitals of Brooklyn for twenty years. He was regarded as an able physician and an unusually efficient officer in the administration of the affairs of the institution under his care.

Facial Epithelioma Treated by Methylene Violet.—At a recent meeting of the Paris Medical Society M. de Castel described the treatment of facial epithelioma by methylene violet, which he has followed for the last two years. Every third day he applies to the diseased part a solution of methylene violet, 20 grains, and alcohol and glycerin 1 dram of each. After two weeks of this treatment a solution of chromic acid (1–5) is substituted for a few days, and then the methylene is used again. Vegetations should be scraped off to insure penetration of the drug.

ORIGINAL ARTICLES.

THE PRACTICAL VALUE OF THE RÖNTGEN-RAY IN THE ROUTINE WORK OF SURGICAL OFFICE PRACTICE.

BY MAURICE H. RICHARDSON, M.D.,
OF BOSTON, MASS.;
VISITING SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL;
ASSISTANT PROFESSOR OF CLINICAL SURGERY,
HARVARD UNIVERSITY.

THE object of the present communication is to illustrate the usefulness of the Röntgen-ray in the daily office work of the busy practitioner. The results which I have obtained in X-ray photography, as shown by the accompanying illustrations, are not, of course, to be compared with those from elaborately and expensively equipped laboratories and hospitals, for they were all taken in connection with my routine office practice. They have been selected from a large number to show the value of skiagraphy in the every-day work of one who knows nothing about photography, nothing about electricity, and but little about physics; who, in short, knows just enough of the principles involved to enable him to place the patient, the tube, and the plate in a proper position, and to turn on the current.

A further object of this paper is to show, if possible, that no surgical consulting-room is fully equipped without an apparatus for X-ray investigation. Doubtless the application of this device to medical diagnosis is quite as important as to surgical, but this question I leave to others more competent to judge.

In the course of the past three months I have been able not only to make accurate diagnoses in many cases, in which accuracy was impossible without the X-ray, but also to avoid serious mistakes in the investigation of fractures and dislocations. I have been able to watch the growth of an osteosarcoma until, from having invaded half the radius, it had destroyed the whole; to ascertain the situation and extent of patellar and other fractures when such knowledge was of great value, and could have been acquired in no other way. In other instances I have been surprised to see the excessive malposition of fragments which, by former methods of examination, seemed to be in unusually good approximation. It has been possible also to detect foreign bodies in the trunk and in the extremities, with a certainty which seemed extraordinary. Results thus obtained in every-day work by one so ignorant of the subject, lead to the belief already expressed, that the X-ray apparatus is indispensable to the consulting-room; that it is as essential to the surgeon as the mirror to the laryngologist, or the stethoscope to the general practitioner.

The cumbersome and expensive apparatus of the laboratory, of the hospital, or of the expert, seems unnecessary in connection with every-day skiagraphy —as unnecessary as a knowledge of cathodes and annodes, of poles and coils. The technic of skiagraphy, like that of the telephone and phonograph, should be of the simplest kind, and should require only the most elementary knowledge. Not that a knowledge of, and taste for, electricity and physics is useless, but for the general application of skiagraphy such knowledge and aptitude is not necessary.

The essentials, therefore, of an X-ray apparatus for general office work, both in fluoroscopy and in photography, are (1) simplicity, and (2) ease and rapidity of application. It is extremely desirable that the apparatus, of whatever form, should be connected with the street electrical mains. Storage-batteries are less convenient, though they may be used when connection with the street-currents is impracticable. That form of Crookes' tube is of the greatest value which is not easily disarranged or broken, and which can be easily adjusted in different positions. The sole efforts of the surgeon should be directed to the adjustment of the patient and the tube, and to the use of the fluoroscope, and of the photographic plate. Impairment or complete arrest of even the simplest and best machinery must of necessity take place, from the very nature of the process—accidents which cannot be prevented even by those who are most familiar with electrical machinery. It is essential, therefore, that the apparatus should be supplied by responsible firms who are prepared, when summoned, to respond at once by sending expert repairers. In this respect the X-ray apparatus should be on the same footing as the telephone, the phonograph, and the typewriter. Upon this point considerable stress should be laid, for the breaking down of an apparatus in the middle of an office hour, when, perhaps, appointments have been made for its use, may subject both surgeon and patient to inconvenience and annoyance.

The method should be capable of rapid application. Many machines require so much time for their adjustment that they cannot be recommended, even if their results are superior to those of a method more

speedily applied. The one with which the accompanying illustrations were taken required no preparation whatsoever. The current (a direct one derived from an Edison light fixture in the wall of the room) passes through various machines to the Crookes' tube. The most important part of the apparatus is, I believe, a Tesla coil immersed in oil. The tube is so mounted that it may be placed in any position. By turning one lever, a portion of the machinery begins to move; by turning a second, the tube is excited and the ray is produced. The whole in its application is simplicity itself. Should the apparatus fail to work, the company at once sends a man to put it in order.[1] In many cases, particularly in examinations of the hand or the foot, a minute or even less is sufficient to give all the necessary information; in others, especially in examination of the thick parts—the shoulder, the knee, the trunk, for example—a longer time is necessary. In ordinary cases of fracture, dislocation, or presence of a foreign body, the use of the fluoroscope requires not over five or ten minutes—a period of time which would be a short one for making a careful diagnosis in obscure cases under former methods of observation. I have used the Carbutt plate of various sizes. After an exposure of from thirty seconds to fifteen minutes, the plates are labeled, put one side, and sent when convenient to the developer.

The value of the X-ray in office work is conspicuous in the detection of fractures and dislocations of the bones; in the demonstration of integrity whenever suspected fractures and dislocations do not exist; in the detection and localization of foreign bodies; in the diagnosis of growths composed wholly or in part of bone. It has, of course, other and less important uses. Unless the surgeon has the apparatus at his elbow, this information can be obtained only by sending the patient to a hospital or to an expert; even then, the surgeon must depend upon an oral or a written opinion, or upon a photograph, unless he goes himself with the patient—reasons which themselves justify the assertion that every surgeon should do his own skiagraphy. In recent fractures—chiefly of the upper extremities, the clavicle, and the ribs—the exact position of the fragments, before and after reduction, can be made out. With the aid of an assistant a faulty adjustment may be rectified at once. Displacement of the fragments may be discovered long before the time for reapplication of the splints. In those fractures of the lower extremities which present themselves at the office, the same information may be obtained. Indeed, an early fluoroscopic examination of every fracture may soon be required of every surgeon for the protection of the patient, and an early photograph for the protection of the surgeon.

In old fractures the information to be gained by the method under consideration is often invaluable, for only in this way can we determine the position of fragments, the point of impingement, and the cause of impaired functions. Here, as in most X-ray work, the fluoroscope gives vastly more important information than the photograph, because one sees in succession the parts from every point of view.

FIG. I.

CASE II.—Fracture of both bones of the forearm. Condition ninety-six days after the accident.

Dislocation of the extremities, old and new, can never be overlooked in fluoroscopy. The slightest variation from the normal is immediately visible in an extremity, below the shoulder or the hip. Even in the shoulder an obscure dislocation can generally be detected, unless the parts overlying the bone are unusually thick. The occasional failure to detect a dislocation of the elbow—a mistake with which the

[1] For four weeks this has been unnecessary. I have used the same tube as often as occasion has required, and nothing whatever has been done to the machinery or to the tube.

most experienced are sometimes confounded—is impossible if the surgeon, as a matter of routine, examines with the fluoroscope. I have overlooked a backward dislocation of both bones of the forearm during twenty weeks' constant observation—an error in which my colleague shared. This fact alone justifies the proposition upon which this communication is based—that the new method of observation is one of the essentials of every-day examination. In another instance, that of a man of sixty, the physician in attendance was sure that there was an unreduced dislocation of the humerus. In spite of careful and repeated examinations by the usual methods, I was

Fig. 2.

Case VI.—Osteosarcoma of the radius demonstrated by the skiagram. Previous diagnosis was aneurism of the radial artery.

not absolutely convinced that the head of the bone was in its proper place until I examined the shoulder carefully with the fluoroscope from several points of view.

In ununited fractures, especially of the humerus and of the forearm, the situation of the bone can be detected with great ease. In one instance the physician blamed himself, and the patient the physician, for a non-union of the humerus, when a careful examination with the fluoroscope showed that the bones were in perfect apposition. What prevented the union of the humerus it was impossible, of course, to say; it was nevertheless a great satisfaction to know that the non-union did not depend upon any faulty position of the fragments.

In the detection of foreign bodies the apparatus is, of course, indispensable. Two or more points of view are essential to determine by triangulation the exact position of the body.[1] The demands from this source are, however, infrequent. As in other X-ray examinations, the fluoroscope possesses far greater value than the skiagram. Other not infrequent uses for the X-ray in general surgical practice are the demonstrations of bone diseases—exostoses, tumors, loss of substance, irregularities in contour, and variations

Fig. 3.

Case VIII.—Compound fracture of the tibia and fibula. Skiagram taken three months after the accident.

in size. In some instances, notably of osteosarcoma, it is possible to detect the growth in its early stages, as soon as the density and contour of the bone is affected. Such a growth may be watched from week to week; the bone may be seen gradually to melt away before the invading neoplasm. In tumors of undoubted bony origin deductions based upon density may easily be made. Exostoses, especially of the extremities, often present pictures of the greatest detail and accuracy (Fig. 3). Irregularities in outline from erosions, necroses, bony deposits, in fact all forms of bone-disease attended by change in form, widen still

[1] Trowbridge, *American Journal of Science*, vol. i, 1896.

further the scope of skiagraphy. It must be borne in mind that all the investigations detailed in the foregoing paragraphs may be made in the course of the ordinary surgical examination.

The following cases have been selected from a large number to illustrate the foregoing remarks:

CASE I.—July 14, 1896: Mrs. A., aged thirty-two, sustained a fracture, July 1st, of both bones of the forearm. The fracture had been reduced immediately by a surgeon of great experience. By ordinary methods of examination, the arm seemed in perfect condition; in fact, a more perfect approximation of fragments could hardly be imagined. A skiagram showed the radius in good position, the ulna with a marked displacement of the lower fragment. The patient made an excellent recovery, however, without perceptible deformity or loss of function.

CASE II.—October 5, 1896: Mrs. B., aged thirty-two, fractured both bones of the left forearm, June 26th, by being thrown from a bicycle. The arm was placed in a metal splint half an hour afterward by a physician. On October 5th, I found a fracture of both bones of the forearm, with considerable deformity and serious loss of function, both as to rotation and flexion of the hand. The skiagram (Fig. 1) shows the position of the bones and the amount of deformity. The fluoroscope gave me a most perfect idea of the extent and nature of the displacement. In spite of the displacement, massage by Dr. Graham has considerably improved the arm.

CASE III.—October 10, 1896: Miss G., aged twenty-seven, fell, January 10, 1896, in the street and fractured the right patella. She was kept in bed, with the usual treatment of such injuries, for three months. A second fall resulted in a refracture, with excessive separation of the fragments of the patella. The fluoroscope showed that the lower fragment was directly over the articulation between the tibia and the femur; that the upper fragment was some four inches higher; that there was a third small fragment loosely attached to the lower one, and slightly separated from it. This fragment was shown to be also partly divided; it could not be detected by digital examination. The seat of injury was exposed on October 13, 1896, and, after much difficulty, by cutting the tendon of the quadriceps above and below the patella, the parts were brought into position. The small fragment interfered so much with approximation that it was entirely removed. The patient has made a good recovery.

CASE IV.—October 13, 1896: Mr. C., aged sixty-two, had been troubled for six years with a painful thickening of the terminal phalanges of the great toe of the right foot. Digital examination seemed to indicate a thickening of the bony parts of this toe. A skiagram showed most beautifully all the bones of the foot, but nothing could be seen indicating disease of the bone. The demonstration was very satisfactory, and solved the question of operative interference.

CASE V.—October 16, 1896: G. B., a boy of twelve, had been injured in the left hand, two weeks before, by a bullet from an air-gun. It was not supposed possible by the attending physician that the bullet had penetrated the palm. The fluoroscope showed plainly a small metallic object over the distal extremity of the middle metacarpal bone. A side view showed the depth of this bullet in the palm. Under cocain the bullet was removed.

CASE VI.—October 17, 1896: General W., aged fifty-nine. This gentleman had had for five months a painful swelling in the right wrist. By means of the fluoroscope the ulna was seen to be intact, the radius to terminate abruptly in the faint shadow of the carpal tumor (Fig. 2). A thin shell of the radius could be seen remaining. The diagnosis of osteosarcoma of the radius, made from the history of the case and from inspection and digital examination, was practically proved by the fluoroscope and by the skiagram. A previous consultant had assured this patient that the tumor was an aneurism of the radial artery. In a second skiagram, taken a month later, the shell of bone had entirely disappeared, a fact that demonstrated the bony origin of the tumor and the rapidity of its extension. The arm was amputated, and the disease proved to be an osteosarcoma of the radius.—In a precisely similar case, Mr. F., aged seventy-three, a tumor of the left wrist was diagnosticated beyond a doubt by the Röntgen-ray. In this case, skiagraphed by an expert, the bony structure of the tumor could easily be seen. The arm was amputated after the incision of the tumor and the microscopic demonstration of its nature.

CASE VII.—October 17, 1896: Mr. P., aged twenty-seven, presented himself with a fracture of the patella of three months' standing. The fluoroscope and a skiagram showed a ligamentous union of a fracture in the lower and middle thirds of the patella. It was proposed to allow the man to go about his business. The fragile union, clearly demonstrated by the X-ray, alone justifies the opinion that he ought not to use the limb freely till the expiration of six months.

CASE VIII.—October 19, 1896: Mr. J. M., aged sixty, had received from a fall a compound fracture of the left leg. The bones of the tibia and fibula had been extensively comminuted, with laceration of the skin. He was under my care at the Massachusetts General Hospital, where he remained some three months. On his discharge from the hospital the leg was perfectly straight; there was no impairment of the function of the ankle, and the union was unusually firm; yet a rather poor photograph clearly shows the extraordinary position into which the bones had been adjusted (Fig. 3).

CASE IX.—L. S., a girl of thirteen, had suffered for nine months with a large painful tumor of the left thigh. After amputation at the hip joint an X-ray photograph was taken of the tumor. The relation of the tumor to the femur, and the involvement of the bone were more clearly shown than was possible in any other way. The growth was an endothelioma (Wright). The patient made a good recovery.

(To be continued.)

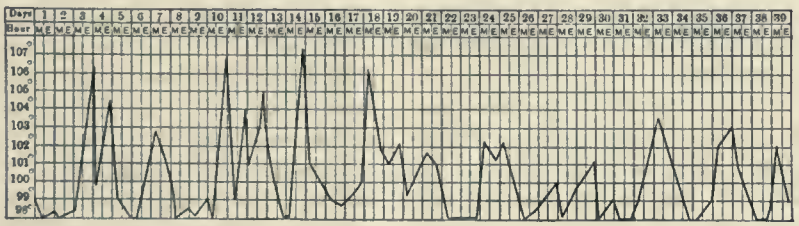
BEST METHODS OF EXAMINING SICK CHILDREN, WITH A CONSIDERATION OF SOME OBSCURE OR RARE MALADIES.

BY J. LEWIS SMITH, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO THE NEW YORK FOUNDLING ASYLUM.

THE examination of children in sickness is surrounded with difficulties which do not occur when the patient is of a more advanced age. The young child cannot describe its suffering, or tell us the seat of its disease; many of its ailments are peculiar, are more concealed, and require more time for investigation and exact diagnosis than the maladies of later life. Therefore, the physician who wishes to excel as a pediatrist must not expect to make a brief visit when summoned to a case, but must remain long enough to learn all the essential details of the malady. Upon visiting a sick child he should enter the nursery quietly, preceded by the mother or nurse, and taking a seat at a distance from the patient, and without appearing to notice him, should learn its history and the particulars of its sickness. With the information thus obtained, and a careful observation of the symptoms, so far as they can be observed at a distance, the experienced physician can often make a diagnosis, which a closer examination shows to be correct. In some instances this distant examination gives a more accurate idea of the nature of the malady than is to be obtained by a closer inspection. The pain of an otitis media is indicated by the infant carrying its finger to the ear, but it does not do this if frightened by the near presence of a stranger.

Attempts to amuse a sick child are always proper, and the physician should endeavor to accommodate himself to the degree of mental development of his patient. The child should feel that he has a friend and playmate in the doctor, and he will then act in a more natural manner, and with less concealment. In my practice, the percussion-hammer, and the prescription-paper and pencil, used for amusing the patient, often divert his attention from his sickness, and by this occupation of his mind his symptoms usually become more manifest. One of the most distinguished pediatrists in America has a soft, melodious chime connected with his watch, and this attracts and delights the little patient, if he be not in too much pain, and he submits more readily to an examination. Force should never be used except in the case of the restraint necessary for the inspection of the fauces. A physician who endeavors to overcome the dread and resistance of a sick child by threats and scolding will never be successful in treating children. After the history has been ascertained (which should include the age, mode of feeding, previous diseases, and in some cases, the health of the parents, together with the symptoms, manner of commencement, and duration of the present sickness), the physician is prepared to approach the patient. No physician need be told how important it is to ascertain the temperature, but in an emotional child, excitement, as that produced by fright, may cause such a sudden increase as may prove misleading. The following case is an example of this:

A female child in its second year, wetnursed by its mother in the New York Infant Asylum, during my visits in 1894, and carefully attended by the resident physicians, Drs. A. and E. Parry, had a mild intestinal catarrh, which did not, however, appreciably affect the temperature. The infant



was extremely emotional. The sudden entrance of a stranger, or his attempts to hold it, or the slamming of a door, caused the high and transient elevations shown in the accompanying chart.

A physician examining a case of this kind would probably make an error in diagnosis, if he did not remain long enough to witness the decline in the fever. Instances of such great variations in temperature from the emotions are not common, but that they do occur should be borne in mind. A young musician of this city immediately before he appeared upon the stage always had a temperature of 102° F.; at other times it was normal. A resident physician of the Charity, now City, Hospital, at one time had a dangerous attack of typhoid fever, by which he was much reduced. The fever finally disappeared, and he began to convalesce, when some friends presented him with a gold watch. The gift took him by surprise and his emotion was so great that it caused his temperature to rise to 103° F.

To prevent any possible aberration from fright or excitement, it is better that the temperature of a child

be ascertained by the mother or nurse before the approach of the physician.

During my long service as one of the physicians to the N. Y. Foundling Asylum I have attended many infants for whom breast-milk could not be obtained. Most of these children had been left at the Asylum doors, and were under the age of two months, and many under one month. There being a large maternity service in this institution, the breast-milk was obtained in as many instances as possible, and those infants receiving it, as might be expected, did better than the bottle-fed babies. The death-rate of the latter was always large, and the most certain sign of the near approach of death was the occurrence of a subnormal temperature. The fall of temperature, at first slight, gradually increased, and when it had descended to 96° F. death uniformly occurred in two or three days, notwithstanding active stimulation. In weak and wasted infants suffering from malnutrition, therefore, a persistent subnormal temperature must be regarded as a very unfavorable prognostic sign.

No one need be told of the importance of observing the presence of abnormalities in the state of the eyes. Dilatation, inequality and sluggish movements of the pupils, oscillation, and strabismus, occurring during the course of an illness, are unfavorable diagnostic and prognostic signs, since they are indicative of cerebral disease.

Rachitis I find, in its early stages, is often overlooked or wrongly diagnosticated. The late Professor Henoch of Berlin has said that rachitis has increased enormously of late in the cities of central and northern Europe; I have found it common in its worst form in Italian immigrants and American negroes, and this is probably due to the poor diet and the unsanitary condition in which they live. I attribute the large increase of rachitis in this country partly to the pauper immigration, and partly to the extensive use of proprietary foods, without any, or with too little, milk. I have examined the composition of thirteen of the commercial foods, and I find that nine of the thirteen contain less than one per cent. of cream. It is sufficient for the present purpose to draw attention to the increasing frequency of rachitis in America, either as a complicating or primary disease, believing that if the fact of its frequency were generally known, the error of a mistaken diagnosis, in its early stages, would be less common.

In diseases attended by emaciation the brain wastes in the same manner as other parts of the system, and if the sutures and fontanels are not closed, and the cranial bones are thus movable, the frontal and occipital bones are depressed and overridden by the parietal. This fact has led to serious mistakes in diagnosis. With the exception of those abnormalities in the shape and development of the cranium, which result from, and pertain to, rachitis, all will agree that in following the advice given by Rilliet and Barthez to "study cerebral symptoms with care," the anterior fontanel will require more attention than any other part of the cranial arch. We all know the significance of a tense and elevated fontanel, occurring without premonition, but attended by fever, and not abating when cool applications are made to the head. In infants in previous ill health, who are much emaciated, the brain, as has been said, participates in the general waste, and if tubercular meningitis, which is not uncommon, occur, with considerable increase of the cerebrospinal fluid, this increase, as I have observed, does not equal the waste, and the fontanel remains depressed. This fact should be borne in mind to prevent error in diagnosis.

Cases are by no means rare in which faucial inflammations of a grave nature are overlooked in their beginning. Mothers, and sometimes physicians, have informed me that the symptoms of the case under examination did not indicate any involvement of the fauces, when inspection revealed the presence of disease which urgently required treatment. A nasal discharge (though slight), huskiness, or other change in the voice from the normal, or an occasional cough, should direct attention to the fauces and lead to their examination. The physician will never regret that he has made this inspection, and often the whole line of treatment will be changed. Without such examination, I have known malignant diphtheria to be mistaken for mumps, and mild diphtheria, with but little tenderness and swelling, to escape notice entirely. Inflammation of the air-passages in infancy and childhood is in many instances trivial, and soon begins to abate, but in a severe form is dangerous, and even fatal; and, from its frequency, it requires a careful examination before diagnostic and prognostic opinions are expressed. Infantile bronchitis, in its commencement, though confined to the larger tubes, if attended by restlessness and fever, should not be made light of. The inflammation is probably pursuing a downward course. Bronchopneumonia is especially a disease of infancy. Unlike the adult pneumonia, it is seldom accompanied by the brick-dust sputum, and bronchitis being a prominent element, a cough is frequent from beginning to end. In this respect it is unlike pleurisy, which, even in the purulent form, sometimes never gives rise to cough during the entire course of the disease. There are other diseases of the pulmonary and circulatory systems in children which are interesting, and which should be carefully considered before a diagnosis is made, but we must pass them by.

One disease I have not infrequently observed in ill-fed and anemic children, as well as in adults. There is tenderness and dull pain, increased by pressure, over a certain area, whether upon the forehead, face, chest, abdomen, or elsewhere. Pressure along the spine and over the rootlets of the nerves which supply the affected part is not only painful at the point of pressure, but it intensifies the habitual pain from which the patient suffers. It has been variously designated as spinal affection, spinal irritation, hyperesthesia, etc. The late Professor Austin Flint was among the first to direct attention to this disease. In 1844 he published a statistical paper descriptive of what he called "the spinal affection," and in his classical treatise on the "Principles and Practice of Medicine," 1886, he designated it "spinal irritation." To my knowledge, this malady is often mistaken for chronic indigestion, gastro-intestinal catarrh, or subacute pleurisy, and if the patient be treated according to one of these diagnoses, he is certain to be made worse. The symptoms of "spinal irritation" and vertebral caries are, in some cases, very similar, but it is not difficult to distinguish one from the other if the mode of examination given in orthopedic treatises is carried out. Dr. Flint once told me that when in Paris he attended the clinic of a distinguished physician, whose name is favorably known in both hemispheres, and a case of abdominal tenderness was presented. After an examination, the professor diagnosticated the condition as peritonitis, and courteously allowed him to examine the patient. Pressure upon the spine elicited pain, which was felt not only along the spine, but over the abdomen. Flint recognized the disease which he had studied so carefully, and expressed the opinion that it was of nervous origin, resulting from anemia, and was not inflammatory—an opinion in which the distinguished clinical teacher concurred after further examination. When we consider that this mistake in diagnosis was made by a physician of great renown, and if not rectified would have led to improper treatment, how important it is that the statistical monograph written by Austin Flint fifty-two years ago should be carefully perused, and the facts which he forcibly presents be impressed upon the memory!

Another disease, the early diagnosis of which is not difficult, is intestinal intussusception. In a considerable proportion of these cases the displacement is not diagnosticated until the chances of recovery are slight. In many patients the invagination takes place by the prolapse of the lower part of the ileum through the ileocecal orifice. This causes swelling and hardness, which may be mistaken for appendicitis. The diagnosis of intussusception is, I think, not difficult, for in whatever part of the intestinal tract it is located, the occlusion is usually so complete that, after the rectum is once washed out, only blood, or blood with mucus, escapes from the invaginated gut. This character of the discharge differentiates the condition from appendicitis, which is not attended by bloody evacuations.

I have heard it stated by some of the oldest physicians of New York that during their entire professional life they have from time to time been summoned to attend children, even as young as two or three years, who have had a fever, which, through want of accurate knowledge of its nature, they have designated malarial. The younger physicians, following their seniors, have adopted the same nomenclature, and, though a false designation, it is likely to be perpetuated. This fever, as I have observed it year after year, occurs during any season, but appears to be most frequent in the autumnal months. Ordinarily it comes on gradually, with malaise, chilliness, anorexia, headache, moderate thirst, weakness, and a dull expression of face. The fever is constant, varying in degree at different times in the twenty-four hours, being usually highest in the evening and at night. A slight cough may also be present. In uncomplicated cases, the most thorough examination fails to reveal a local cause adequate to produce the fever. The duration of this malady varies; it may not be longer than nine days, or it may last for some weeks. Quinin has no appreciable effect, unless that it diminishes in slight degree the febrile exacerbations. There is commonly no marked abdominal tenderness or decided tenderness or enlargement of the liver or spleen, and in most cases no rose-colored eruption. A physician of this city has informed me that some twenty-five years ago he attended a case of this fever, which was unusually protracted. The late Professor Alonzo Clark, who was also in attendance, stated that for many years he had taught in his lectures that this mild fever in children was a form of typhoid, but he had never had the opportunity to verify his diagnosis by an autopsy, as he had never observed a fatal case; but a former pupil of his, practising in a New England city, had recently lost a child from this fever, and being permitted to make an autopsy, had found distinct typhoid lesions. Since Professor Clark's death his opinion of the nature of this fever has been abundantly verified by clinical observations and autopsies. Moreover, in some of the instances, the children, mildly sick in the manner which I have described above, evidently communicated the fever in its usual form to the nurses. Thus, in my practice, two children had the fever in its usual mild form, refusing to remain in bed, and sitting in a listless manner most of the time close to the fire. In about two weeks, when they began to

convalesce, the nurse sickened with the same disease, which continued in a very severe form for thirty-five days.

The term malarial fever, so commonly applied to the mild typhoid or enteric fever of infancy and childhood, is, therefore, a misnomer, and in the present advanced state of pediatric knowledge should be abandoned.

UNILATERAL ALBUMINURIC RETINITIS, WITH CASES.[1]

By G. E. DE SCHWEINITZ, M.D.,
OF PHILADELPHIA, PA.;
PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE, ETC.

USUALLY both eyes are affected in albuminuric retinitis, although it is common to find more extensive lesions in one eye than in the other, just as one kidney is often more diseased than its fellow. In many cases, in the early period of the disease, the visual defect is asymmetrical, one eye exhibiting retinitis or neuroretinitis, while the other is still free from inflammatory or degenerative changes. Subsequently, however, in the great majority of cases, both retinas become affected.

In regard to the frequency with which unilateral cases occur, opinions differ. Thus, Gowers[2] says: "Both eyes are almost invariably affected," while Knies[3] declares "Unilateral cases are not a rarity;" and, again,[4] "Unilateral retinitis albuminurica is not extremely uncommon."

In confirmation of Knies' declaration, a number of cases of monolateral neuroretinal lesions attributed to so-called chronic Bright's disease may be found scattered through medical literature. Thus, Despagnet,[5] in his statistical report of the retinal diseases seen in the Galezowski clinic, records a case of unilateral retinitis albuminurica; the right eye was affected, the left being entirely normal. Yvert[6] observed in a forty-eight-year-old patient unilateral, left-sided retinitis albuminurica, with characteristic changes in the macula. At the autopsy, only the right kidney, in a state of parenchymatous inflammation, was present. Brunet[7] describes a case of right-sided anasarca with right-sided retinitis albuminurica. W. Cheatham[8] records "a perfect picture of neuroretinitis albuminurica" of the left eye in a girl aged fourteen, whose urine contained cysts and albumin. The right eye was healthy. Henry Eales[1] reports a case of supposed unilateral albuminuric retinitis, the visual disturbance appearing one day after an injury to the left loin. Three weeks later, the right eye being normal, there were in the left eye neuritis, and exudates in the macula. The final outcome of the case was an atrophic disk, with glistening patches in the macula and degeneration of the choroid. Albumin, which was present, gradually disappeared; casts were not found. Bull, in his analysis of 103 cases,[2] remarks: "Both eyes were affected at the time of the examination in fifty-four (54) cases, and both eyes became affected while the patients were under observation in ninety-three (93) cases." The natural inference from this quotation is that there were ten (10) unilateral cases. Almost ten per cent. of one-sided retinitis albuminurica is a clinical observation somewhat at variance with the accepted ideas on this subject, and therefore I wrote to Dr. Charles S. Bull with reference to this point, and received the following reply:

> You are quite correct in inferring that in the paper written by me in 1886, and referred to by you, there were ten cases of unilateral neuroretinitis, which remained so until the end of the patient's life. None of these cases came to autopsy by me, though in two an examination was made *post mortem* by another physician. It is, perhaps, pertinent to state that in these ten cases the renal disease was severe in its onset, and rather rapid in its progress, and in none of them lasted longer than five months. I have under observation now a case of nephritic neuroretinitis, confined to one eye, which has lasted eight months, and the other eye is, *as yet*, intact.

These cases will suffice as examples of unilateral neuroretinitis of nephritic origin scattered through literature, and also suffice to show that it is not an uncommon phenomenon. I have no doubt there are many more, as I have not attempted an exhaustive search.

My personal experience comprises the examination of two cases. One of these I have briefly recorded elsewhere.[3] This patient was a colored man, who came from the medical clinic of the Hospital of the University of Pennsylvania to the Eye Dispensary, with the report that he was suffering from Bright's disease, and requesting an ophthalmoscopic examination. The fundus oculi of one eye was practically normal, while the other showed an extensive neuroretinitis. The patient was not again seen, so far as I am aware, and I have no knowledge of his future history or of the future conduct of the case.

The case which I particularly wish to report to-night has been under observation for some time, and is as follows:

Stephen Punnell, a negro laborer, aged fifty-one years, came to my dispensary in the Philadelphia

Polyclinic on the 13th of June, 1896, complaining of loss of vision in his right eye. He also stated that he had pain in the lumbar region, and had noted increased frequency of micturition.

For the history of this patient, and for the physical examination, I am indebted to my assistants, Dr. Frances Janney and Dr. Mary Getty, as follows:

The patient's mother died at the age of fifty-five, and before death "had swelling in both feet." His father died, aged sixty-nine, from paralysis. The patient's habits are good. He has never used liquor, and there is no history of syphilis. His previous illnesses were measles, whooping-cough, typhoid fever (in 1869), and bilious intermittent fever, two years ago. He dates his present illness to three years ago; but declares he has suffered from lumbar pain since the Civil War. Physical examination reveals a normal heart and normal cardiac action.

Ocular examination: Vision of the right eye $\frac{6}{15}$, unimproved by glasses; of the left eye, after the correction of a low grade of hypermetropic astigmatism, $\frac{6}{4}$. There were no abnormalities of the pupil-reflexes or of the external ocular muscles.

The pupil of the right eye having been dilated with cocain, the following lesions were discovered: A disk with congested surface, but clear edges; extensive flame-shaped and irregular hemorrhages occupying the temporal region as far as the macula, and somewhat beyond it, and the upper retina nearly to the periphery of the eye-ground; a few scattered hemorrhages on the nasal side, the entire lower half of the eye-ground being free from gross pathologic changes. In addition to the hemorrhages, there were numerous roundish and elongated yellowish-white patches, some in close proximity to the hemorrhages, and evidently representing areas of fatty change, as well as patches of degeneration, the sequel of previous hemorrhagic extravasations. The arteries are about normal in size, the veins somewhat distended, and slightly tortuous.

It will be noted at once that the lesions are not typical in the sense of a star-shaped figure in the macula and a "snow-bank appearance" around the disk, but represent those which we are accustomed to associate with thrombotic conditions in the retinal venous circulation. Closer examination of the distribution of the veins makes it evident that the upper and lower temporal vein are fairly normal in constitution, although in places somewhat covered above by exudation. The lower nasal vein is also well marked, while the upper nasal vein, from its point of entrance into the optic disk to about one-half the disk diameter, upward and inward, appears to be obliterated, or is present only as a very fine thread. Beyond this point the vein can be readily traced. This appearance adds still more to the supposition that the primary lesion in this case was a thrombosis of a venous branch, rather than a true retinitis or neuritis. We have, in other words, a condition of apoplexy of the retina, rather than a neuroretinitis.

In the left eye the surface of the disk was about normal in appearance; there was some fine white haze in the immediate neighborhood of the disk, but no hemorrhages, no splotches, and no areas of degeneration. The refractive error was a hypermetropic astigmatism ($+.50s.\bigcirc+.50c.$ axis 180), and with this glass, vision, as before stated, was $\frac{6}{4}$.

The patient was referred to the medical dispensary for general treatment, and Dr. Riesman has kindly furnished me with the results of the urinary examination. An average examination is the following: *Microscopic:* An unusual number of oxalate-of-lime crystals, many uric-acid crystals, and numerous broad granular casts. *Chemic:* A large amount of albumin, no sugar; blood, by the guaiac test. Specific gravity varying from 1011 to 1031.

From that date to the present time the patient has remained under my observation, and under suitable treatment from my medical *confrères*. Abundant clinical examinations indicate a typical case of interstitial nephritis.

The following changes have occurred in his fundus oculi: Decrease in the areas of hemorrhagic extravasation, with development of larger areas of degeneration, and well-marked lines of perivasculitis. The vision at the present time remains as before, $\frac{6}{15}$ in the affected eye and $\frac{6}{4}$ in the left, or unaffected eye, which continues to be normal in appearance.

In regard to the etiology of unilateral neuroretinitis, or so-called hemorrhagic retinitis, in Bright's disease, various theories may be utilized. Yvert explained his case of one-sided retinitis albuminurica by assuming an irritation of the sympathetic nerve of one side, due to a unilateral affection of the kidney. It will be remembered that at the autopsy on his patient the left kidney was absent. He based his explanation on the opinion of Potain, who believed that the one-sided anasarca of Bright's disease, which has been observed after contusion of the kidney, and also in Bright's disease without such history, was explainable by an abnormal action of the sympathetic nerve. Eales, whose patient also suffered from an injury of the loin, with rapid unilateral retinal affection and albuminuria, is inclined to accept Yvert's view of irritation of the sympathetic as the most plausible, under the circumstances.

Although we have one case substantiated by autopsy in which one kidney alone, in a state of parenchymatous nephritis, was responsible for a unilateral retinal lesion, as Knies remarks, this observation does not permit the inference that in disease of one kidney the retinal affection will be one-sided.

In a case like my own, the starting-point of the disease is apparently not in the retina, but rather in the vessels of the optic nerve, the retinal changes, hemorrhages, spots of degeneration, etc., being secondary to this condition, and I suspect that in some of the other cases reported as unilateral neuroretinitis the same lesions may have been present. It is by no means a new observation. Knies has seen

hemorrhage into the optic nerve of one eye, with blindness, in a case of albuminuria; one year later the opposite eye was attacked by a pure hemorrhagic retinitis. Hemorrhages in the optic nerve have been demonstrated *post mortem* a number of times under these circumstances, particularly in the investigation of Herzog Karl Theodore, and the etiological relation of nephritis to thrombosis of the retinal vein, or one of its branches, is well known.

A point of some importance is the one referred to at the beginning of this paper, namely, that for a time a unilateral retinal or nerve-head lesion in Bright's disease is common; subsequently the ordinary bilateral character of the affection appears. It is probable that some of the reported unilateral cases have been recorded at a time when the visual defect was still asymmetrical, bilateral retinitis occurring before the termination of the case. It will be remembered that Bull, in his series of 103 cases, found that both eyes were affected at the time of the examination in fifty-four, or about half of them, from which we would infer that the other half were unilateral. Of these unilateral cases, however, all but ten of them subsequently became affected on both sides.

Evidently, as Knies has remarked, unilateral albuminuric retinitis is not a rarity, a certain percentage of cases maintaining monocular retinal lesions until death. In another large percentage of cases the unilateral character of the affection is maintained for a considerable period of time, but ultimately becomes bilateral. An interesting clinical observation in these unilateral cases would result from catheterization of the ureters and separate analysis of the urine from each kidney. My patient has thus far declined to submit to this procedure.

INTRAVENOUS SALINE INJECTIONS IN CONDITIONS OF SEVERE SHOCK.

BY LEWIS A. STIMSON, M.D.,
OF NEW YORK;
SURGEON TO THE NEW YORK HOSPITAL.

THE advantages to be obtained by the intravenous injection of large quantities of the "normal salt solution," during or immediately after operations accompanied by much hemorrhage or shock, are now well understood. It is, perhaps, not so well known that similar advantages may be obtained by the same means in cases of injury followed by marked shock, with or without important hemorrhages externally, or into the natural cavities, or among the tissues of the body. The following cases may serve as illustrations:

CASE I.—A. R., aged thirty-one, was struck, December 17, 1895, on the right side and front of the abdomen, and squeezed against a wall, by a piece of structural iron weighing 700 pounds, which he was engaged in moving. He was immediately brought to the New York Hospital. When I saw him, three hours later, the condition of extreme shock, which was present on admission, persisted; the abdomen was tender and distended, the flanks dull on percussion, and a slight intra-abdominal wave could be obtained. There was evidence of an intraparietal hematoma on the right side between the ribs and the ilium. The urine did not contain blood.

Twenty ounces of the salt solution were at once introduced through the median basilic vein. This was followed by a prompt improvement in the general condition; and as the local signs grew no worse the attitude of expectation was maintained. Complete recovery followed.

CASE II.—Chas. A., admitted to the New York Hospital, December 11, 1895, after having just fallen from the third floor of a house. Several ribs on the left side were broken, and there was extensive emphysema of the chest wall; marked shock.

Twenty ounces of the salt solution were injected into the median basilic vein. Recovery.

CASE III.—James S., admitted to the New York Hospital, December 13, 1895, with fresh burns, covering almost the entire body. Extreme prostration. The patient was placed in a hot bath and received a large saline injection, but died 3½ hours after admission.

CASE IV.—William B., twenty years old, was admitted to the New York Hospital, October 23, 1896, having just been run over by a dummy engine. The left foot and ankle were crushed, the joint being widely opened; compound fracture of the right radius; compound dislocation of the right thumb; simple carpo-metacarpal dislocation; profound shock; semi-conscious.

The left leg was immediately amputated, the patient receiving meanwhile a saline intravenous injection of 34 ounces; this brought his pulse down to 88, but an hour later it rose to 160; a second injection of 34 ounces was then given, bringing the pulse to 120. Recovery.

There is also reason to think that similar advantages may be gained by the same means in severe septic conditions. In July, 1896, I saw in the wards of my friend, Professor Pozzi, in the Broca Hospital, Paris, a woman, who had been admitted three days previously, gravely ill with puerperal septicemia. The only treatment had been the immediate administration of a large intravenous saline injection. This was promptly followed by a marked reduction of the temperature and improvement of the general condition, which still persisted when I saw her. The following case may be quoted in connection:

CASE V.—Chas. L., aged twenty-seven, was admitted to the New York Hospital, December 1, 1896, suffering from general peritonitis, due to perforative appendicitis. The attack began on the night of November 28–29th, about sixty hours before ad-

mission. The abdomen was distended, tense, and painful; the surface dusky; the pulse rapid, small, and of bad quality; temperature 102° F. Fecal vomiting.

The abdomen was immediately opened, and the appendix, which had been completely divided near its base by ulceration, was removed. Several ounces of pus from the neighborhood of the appendix was removed, and then a large quantity of turbid serum from the general peritoneal cavity. The intestines were congested, distended, and coated in many places with a fibrinous exudate. The general peritoneal cavity was thoroughly irrigated and sponged with salt solution, drained with gauze and two large rubber tubes, and the wound partially closed.

The patient's condition, as shown by his pulse and surface circulation previous to the operation, occasioned much anxiety. About 24 ounces of the salt solution were injected by an assistant while I was operating. This was followed by an immediate improvement, which persisted through the day. On the following day the general improvement was maintained, and the local conditions were better, the left side of the abdomen being soft and painless. This continued until December 4th, when the vomiting was renewed, all efforts to secure a movement from the bowels having failed. The pulse again became almost imperceptible, the surface dusky, and the nose cool. An injection of 60 ounces was made, and the same improvement followed, but the vomiting persisted, and the patient died early on December 5th. It seems clear to me that in this case the injection prolonged life fully three days, enabled me to perform the operation and check the peritonitis, and only failed to save the patient because of the persistence of the intestinal paresis.

The good effect of these intravenous injections is doubtless due to the change in the physical conditions created thereby; the intra-arterial pressure is increased, and, presumably, osmosis is carried on more freely. Possibly, too, the presence in the body of the large additional amount of water favors metabolism and excretion, and thus diminishes the production of deleterious compounds and aids the removal of those that are produced.

While no direct curative effect has been proved, yet the injection gives to a patient, who apparently has but a few minutes or hours to live, a respite, during which his organism may recover from the shock received, or throw off a septic assault that is pressing, or during which the physician may, perhaps, successfully employ remedial or helpful measures.

The technic is simple. A sterilized, graduated vessel, provided with a rubber tube about three feet long, ending in a fine pointed glass or metal nozzle, is required. The solution can be readily made by mixing common salt and water in the proportion of ninety-two grains (a large, but not heaping, teaspoonful) to a quart, and sterilizing it by boiling. It should be injected at a temperature of about 105° F. The vein should be exposed, a ligature passed beneath it, and the vein opened by snipping it half across with scissors. The water is then allowed to fill the tube, the nozzle is inserted into the vein, and the ligature tied about it so as to prevent slipping. The vessel holding the solution is then raised two or three feet above the patient, and the solution allowed to run in.

Some deem it simpler and equally beneficial to throw the solution into the subcutaneous tissue by means of a syringe and hollow needle, taking pains afterward to distribute the liquid by rubbing toward the heart.

THE SIGNIFICANCE OF PAIN.

By W. H. THOMSON, M.D.

OF NEW YORK;
PROFESSOR OF THE PRACTICE OF MEDICINE IN THE NEW YORK UNIVERSITY.

WHAT the study of special forms of disease is to the science of medicine, so is the study of the effects of disease, whatever be its special form, to the practice of medicine. If the characters of an affection are sufficiently definite, it is proper to give it a name to distinguish it from other affections. But this designation of diseases by special names may be in practice a hindrance, rather than a help, if it leads to the treatment of diseases according to their names, because even the most special affections may induce derangements which are common to more than one disease, so as to render the state of the patient, rather than his particular disease, the chief concern of the physician.

Viewed under this aspect, certain common, but important, symptoms of disease assume an interest quite their own, sufficient to warrant their being made the subjects of separate study. Their relation to diagnosis, prognosis, and treatment is often of the first importance, and yet this may be but inadequately appreciated amid the desultory reference to them in the symptomatology of special diseases. As a useful introduction, therefore, to the consideration both of general and of specific morbid processes, I would devote a few lectures to some phases of the general semeiology of disease, as illustrated in the case of certain leading symptoms, whose significance always merits special investigation in whatever connection they may occur.

We begin with the subject of "Pain" as a good example of the advantage which the particular study of a single symptom may afford. In diagnostic value alone it is not to be surpassed by any of the common signs of disease, and it would be well, whenever it is mentioned by a patient, to make it the subject of exclusive attention before proceeding to any other

investigation, until both its nature and significance are as fully determined as possible.

The investigation should begin with a request that the patient show just where the pain is felt most, and where it first began. While he is doing so, the gestures which he uses should be carefully noted, as they often afford truer indications than his language does, because verbal descriptions of pain may be extremely indefinite. As a rule, such gestures are characteristic enough to aid materially in the recognition of the particular variety of pain, if not also of the nature of the affection itself which is present, as the following examples will show.

When the pain is due to inflammation, if external, as with a joint, the patient will avoid touching the most painful part, or he approaches it in a very respectful way. Thus, with an arthritis his hand passes over the joint in a hovering fashion. If deeper seated, the gestures are often expressive of the varying kinds and distribution of the pain, according to the texture inflamed. Thus the diffused soreness of a mucous-membrane inflammation causes the gesture of bronchitis to be made with the whole hand laid on the sternum, and then passed over and across the chest. A similar movement of the hand across the abdomen never means a peritonitis, but a catarrhal intestinal inflammation. With pleurisy, on the other hand, the tips of the straightened fingers are used to indicate the stabbing nature of the pain. In peritonitis, also, the tips of the fingers are used, but brought down with much more caution than in pleurisy. In the localized pain of commencing appendicitis, the open hand is used, as with an inflamed joint. In pleurodynia, the whole hand is pressed firmly to the side, to prevent movement of the ribs. In rheumatic fever, the pointing by the patient to the epigastrium or to the xiphoid cartilage, especially if followed by a movement from the precordium up the neck or into the left arm, is significant of cardiac inflammation. So also the gesture in gastritis, whether acute or chronic, is wholly different from that in colic. Inflammatory pains about the head may have very characteristic gestures. The use of one finger-tip to localize it on the scalp is strongly significant of intercranial syphilis. The finger-tips passing up the side of the face and stopping on the scalp an inch below the sagittal suture indicates a pain ascending from a tooth, and should not be mistaken for a trigeminal neuralgia. In conjunctivitis, the hand is laid over the eye. In iritis, the finger is pointed toward it, not touching it, and then passed up the forehead to the inner side of the nose or to the malar process. In glaucoma, the gesture may be reversed, as if the pain was emerging from the orbit. All these gestures differ entirely from those of head-pains not inflammatory. Meningitis, whether cerebral or spinal, is significantly indicated by absence or suppression of gesture, for reasons to be noted further on. The exceptions to this are in some cases of tubercular meningitis. But the gesture of myelitis, with both hands passed from the back across the abdomen, to describe the cord or band-like sense of constriction, is almost itself pathognomic.

On the other hand, the gestures indicating the seat of the greatest pain produced by pressure, as by tumors, abscesses, etc., or cramps, markedly contrast with those of inflammatory pains in showing no apprehension in touching or in moving the part. Here the locality indicated at first by the gesture is of importance to note, and whether, on repeating the question, the same place is again started from, because the patient's hand then moves in a fashion expressive of the extension or radiation of the pain from the original focus, although he may describe the pain as equally present at some distance from the spot first pointed out. Hence, his unconsciously repeating the sign with which he commenced is of much significance. Thus, a patient with a growth springing from the lumbar vertebræ always first pressed the point of two fingers deeply into the abdomen below the umbilicus, while the fingers of the other hand moved over the sacrum, where he insisted that his pain chiefly was. A fixed pain in the back caused by an aneurism is often indicated by the extended thumb, and likewise the pain preceding herpes zoster, but no spinal inflammatory pain will elicit such a gesture, nor will the pains of so-called spinal irritation.

In stretching pains, such as in biliary or renal colic, or cramps, as in lead colic, the contrast to inflammatory pains is shown by the forcible grasp or pressure which the patient makes on the abdomen, while the characteristic radiations of the different varieties may be very plainly represented. Even when the pain has ceased, the gestures descriptive of what he had experienced may be equally conclusive as to their nature.

The gestures expressive of true neuralgic pains contrast throughout with those of inflammatory pains. A functional occipital headache is shown by a friction-like movement of the hand from the neck up, sometimes followed by pressure on the eyes with the fingers. So the hands are used with the firmest pressure in temporal or frontal neuralgias, or the patient may tightly tie a handkerchief around. This proneness to grasp or to press the aching head, as well as to move the aching part, is characteristic of neuralgic pains everywhere in the body. The gestures are also valuable from their indicating the shifting character of neuralgic pains, enough, at least, to dis-

tinguish them from the more fixed pressure-pains of tumors. Special characters of neuralgic pains are frequently most graphically described by the gestures, as in the darting pains of tabes.

Subjective pains, as in hysteria, are very characteristic in their being more numerous and varied than true objective pains can be, and, secondly, in the inconsistency of the gestures with the often highly wrought description of them by the patient. Both the language and the manner of the patient is more like one telling the tale of a woful past experience than of a present reality.

I might multiply many illustrations of the clinical value of gestures descriptive of pain, toward making a right beginning in diagnosis. I have already implied, however, that pains differ much in kind and in character, and hence the necessity of distinguishing their special varieties. For this purpose, I would classify them into six different forms, as follows:

(1) Pains due to inflammation. (2) Pains due to pressure. (3) Pains due to stretching. (4) Neuralgic pains. (5) Subjective pains. (6) Cutaneous reflex pains.

Inflammatory pains have three great characteristics. The first is that pain is elicited by pressure upon, or by handling the inflamed part, and the rule is that pressure produces the maximum amount of pain at the seat itself of the inflammation. This fact is useful in diagnosis, both positively and negatively. Thus, an inflammatory pain in the leg may be due to peripheral neuritis, to sciatica, to hip-joint disease, to gouty arthritis, to rheumatic arthritis, to muscular rheumatism, or to spinal meningitis, and each one of these may be distinguished from the others by appropriate palpation. In peripheral neuritis, pain is most complained of on pressure upon the skin and superficial structures much more than when you lift the whole limb in your hands or move its joints. Sciatica is diagnosed by the special tenderness on pressure at the sciatic notch, along the course of the nerve down the back of the thigh, or deep in the popliteal space, or between the heads of the soleus in the calf; hip-joint disease by pressing the head of the bone against the acetabulum. I have shown[1] that a gouty arthritis may be distinguished from a rheumatic arthritis by the different points of tenderness about most of the joints in these two diseases. In gout, the tenderness is distinctly most pronounced at the condyles; in rheumatism, along the tendons and at their insertions, and not on the condyles. Thus, at the knees, in acute gout, the condyles are very painful on pressure compared with the rest of the joint, while in rheumatism the most pain is elicited by pressure on the tendon of the quadriceps above and below the patella and on the tendons of the hamstring muscles. This same difference in the points of tenderness between these two affections is also well shown in the fingers. The pain of muscular rheumatism in the leg is shown by pressure or manipulation of the muscles themselves, and this serves to distinguish it from pains in the leg in spinal meningitis, where you may manipulate the muscles without pain, but you cannot move the whole leg without making the patient cry out, or, if comatose, groan out from the pain so caused. On the other hand, a child may complain of severe pain on the inner aspect of the knee, but you press the part and it does not increase the pain, which shows that the seat of the inflammation is not there, but, by proper manipulation, may be found higher up—at the hip-joint. Similarly, a child may complain of constant pain in the stomach, and I have known such a case thoroughly dosed for worms; but tenderness on pressure at the eighth dorsal vertebra showed that it had incipient Pott's disease.

Careful manipulation to locate tenderness will frequently reveal the nature of a trouble which otherwise may be very obscure. Tenderness on pressure along the course of an intercostal nerve may dispose of a diagnosis of heart-disease or, as I have twice known, of cancer of the liver.

So tenderness on pressure, highly located, may indicate the presence of a hepatic or of a renal calculus. In the former case, press the tip of the index-finger deeply down at a spot one inch and a half to the right, and an inch below the umbilical line. In renal calculus, standing behind the patient, first place the thumbs of both hands under the last ribs, and then so spread the fingers over the abdomen that when the patient relaxes the abdominal walls by bending well down you can push the kidneys up toward the spine; then, as he straightens up, press the thumbs in strongly, whereupon, if he has a renal calculus, he will quickly bend over on that side. You may further confirm the diagnosis of a hepatic or renal calculus by putting one pole of a faradic battery on the spine, and then suddenly applying the other with firm pressure at the places just indicated, when you will distinctly elicit the same kind of pain which manipulation does. In appendicitis, much is made of the special tenderness elicited by pressure at what is called McBurney's point, on a line midway between the anterior spine of the ileum and the umbilicus.

The second great characteristic of inflammatory pain is that it is increased by any form of movement of the inflamed part, not excepting its own proper functional movements. The inflamed part, therefore,

[1] "Transactions of the Association of American Physicians," Washington, 1896.

is both voluntarily and involuntarily kept at rest as much as possible. This is done by muscular action, the afferent impression of this pain being reflected to all the associated muscles of the part to restrain their action, and even to muscles which, though not usually connected with the function of the part inflamed, yet may disturb it by their movements. Examples of the first kind are seen in the fixity of joints by the contraction of their muscles whenever and as long as the joints are inflamed, while the latter is shown by both the local or general rigidity of the abdominal muscles, according to the local or general state of inflammation underneath. Thus, comparative palpation made by both hands in the iliac fossæ is of help in the early diagnosis of typhoid fever. You can exclude gastritis as the cause of stomach symptoms if there be no rigidity in the epigastrium. In appendicitis, from the commencement of the irritation the muscular resistance over the cecum may have the feel of a solid tumor much before there has been time for exudation or pus-formation. A number of other characteristic and significant signs are thus developed, which point both to the existence of inflammation and to its seat. There is no part of the body, for example, so often moved for purposes of attention or expression as the head. When, therefore, on approaching a patient's bed, you notice that he turns his eyes, but not his head as well, to look at you, the reason may soon be found in rigidity of the muscles of the neck, owing to meningitis. It is a good sign of improvement in such a case when his head acts naturally with his eyes or nods in assent. A healthy child constantly bends or unbends its back, but a child carefully picking up something from the floor by bending its knees without bending its back should lead you to examine it for vertebral disease. There may be lameness from either arthritis or sciatica in the leg, but the muscular actions are characteristically different in each of these inflammations. I need not say how the movements of the ribs in breathing are watched by us for the same reason in examining for phthisis, pleurisy, or pleurodynia. Hence the muscular accompaniments, so to speak, of inflammatory pain are of much service in diagnosis, because all the other varieties of pain have nothing to do with the muscles. The only exception to this statement is in some cases of hysterical muscular contractions with much complaint of pain; but the other features of these cases enable us readily to distinguish them from inflammatory rigidity.

The third great characteristic of inflammatory pain is that it is accompanied by disturbance of the normal function of the injured part. Now this does not happen with the other varieties of pain, at least as a characteristic of them. Neuralgic headache, for example, is not accompanied by delirium or, ordinarily, by intolerance of light or of sound, as the headache of meningitis is. Neuralgic pains in the spine, in the arms, or in the legs do not produce stiffness nor fetter the movements of those parts, whose chief functions are to execute movements, while inflammatory pains do. So the diagnosis between pleurisy and pleurodynia lies in the fact that the pain on movement of the ribs in pleurisy causes the functional symptom of cough, while that of pleurodynia does not, for the seat of the pain is not in the pleura at all. Again, when a pain in the chest is accompanied by an altered ratio between the frequency of the respiration and the frequency of the pulse, we have strong reason from this significant disturbance of a lung-function to suspect pneumonia. If inflammation of the heart or of the pericardium causes pain, it is always accompanied by signs of disturbed heart-action. So gastritis cannot cause pain without being accompanied by symptoms of gastric functional disorder. The same is true of peritonitis, enteritis, or dysentery. I once wondered why a patient who complained of attacks of severe pain just above the pubis had been twice sounded by surgeons for stone in the bladder, when he showed no signs of disturbed function in the bladder whatever. It proved to be due to chronic lead-poisoning from the prolonged use of a hair-dye.

Besides these three great characteristics of inflammatory pains, the sensation itself often varies in kind, according to the tissue involved. The rule is, the softer the texture the more acute the pain; so that it may be described as only dull and heavy, as in inflammation of the liver or in a pneumonia which has not involved the pleura. In inflammations of mucous membranes, the pain, if moderate in degree, is more like a diffused soreness; if severe, it may be termed burning. Whenever griping or bearing-down sensations develop, it is because the inflammatory irritation has extended from the mucous membrane to the muscular coat of the wall of the canal or viscus which the membrane lines. Pain of inflamed serous membranes is much more acute than in the case of mucous membranes, and is apt to be lancinating or stabbing, as indicated by the patient's gesture. Pain of inflamed fibrous tissues, such as muscular fascia, nerve-sheaths, periosteum, dura mater, etc., if moderate, is of a dull, aching character; but if severe, is very violent, on account of the unyielding nature of the tissue. A serviceable indication of the seat of the inflammatory process is afforded by the susceptibility of patients with any form of fibrous-tissue inflammation to changes in the weather. In health, there is a perfect adjustment between the centrifugal pressure of the circulation and the centripetal pressure of the

weight of the atmosphere. Changes in the latter, as indicated by the fall in the barometer on the approach of a storm, are readily compensated for by the nerve-fibrils being readily removed in the softer tissues from unbalanced intravascular pressure, but not so in the denser fibrous tissues. Hence the good, but inconvenient barometers which a gouty man has in his toes, which may ache worse while the sky is yet clear, but which he knows, from experience, means that the clouds are on their way. So a patient with sciatica finds his bed-covering no protection when his leg wakes him in the middle of the night with its observations on the weather out of doors. It is well, therefore, to ask whether a headache complained of grows worse just before a storm, when you have reason to suspect that it is no mere functional trouble, but a cephalalgia of syphilitic origin.

Inflammatory pain is peculiarly local, and therefore referred to the part inflamed, except when the inflammatory process involves the course of nerves. In that case, it may be radiated either along those nerves directly or to some region in nervous association with the seat of the inflammation. Thus, the pain in ulcerative gastritis is often radiated to the sixth or seventh dorsal vertebræ. Inflammation involving the convex surface of the liver affects the distribution of the right phrenic nerve on the under surface of the diaphragm, and from there may radiate to the top of the right shoulder or between the scapulæ. Inflammation of the vertebræ sends pain to the anterior distribution of the surface-nerves. Inflammation of the kidney radiates pain to the testicle and down the inside of the thigh, while inflammation of the fundus of the bladder produces pain felt in the head of the penis. In some cases of inflammation of the prostate, pain is felt in the sole of the foot. In every case, however, these pains can be proved not to belong to the region to which they are referred by the fact that the patient has no objection either to movement or pressure of the part.

The treatment of inflammatory pains is that of the inflammation itself, and hence often different from, if not the reverse of, the treatment of other kinds of pain. The first indication is rest, including the position which assures most rest. After a rheumatic carditis, the patient had better stay three or four months in bed if he still has cardiac pains and a quickened pulse. Nothing is more serviceable sometimes in the later stages of pleurisy than to limit as much as possible the movements of the ribs by firmly strapping the whole affected side of the chest. But the instances in which this principle can be applied are too numerous to mention here. In many acute inflammations, the vascular sedative action of topical blood-letting is often remarkably effective in relieving the pain. On the other hand with the pains of chronic inflammations, the stimulant effect of counter-irritation is preferable, according to the rule that the indications in the treatment of chronic inflammations are the opposite of those for acute inflammations. In traumatic lesions, both the pain and the inflammation are generally treated best by the local application of ice-bags, but cold is useless when the inflammation is due to a general cause in the blood, as in rheumatic and gouty arthritis. Cold applications should be discontinued at once if they cause a neuralgic pain to take the place of an inflammatory pain. Many internal inflammatory pains are best relieved by the sedative properties of moist heat applied to the surface, as by poultices, etc., according to the general law that the cutaneous sensory nerves are always in association with the vascular nerves of the parts underneath. The great drug for inflammatory pains is opium. Next comes aconite, especially in serous membrane and cardiac inflammations. The coal-tar analgesics, so valuable in the other kinds of pain, are comparatively useless in inflammatory pains.

CLINICAL LECTURE.

ANEURISM OF THE AORTA; HYSTERICAL HIGH TEMPERATURE; TREATMENT OF PNEUMONIA.[1]

BY A. ALEXANDER SMITH, M.D.,
OF NEW YORK:
PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE.

CASE I.—This woman is forty-two years of age, has been in this country ten years, is married, and has had several children. She gives a history of having been in good health up to within three months. She then began to complain of pain extending from the lower sternal region to the right side. There was a moderate amount of cough and shortness of breath, the latter becoming more and more pronounced. There is no specific, rheumatic or alcoholic history, and none of accident. I speak of these things in order to exclude certain points in etiology. She has just walked upstairs, and although it has made her short of breath, it has not, apparently, added much to her pain. She has coughed two or three times within the last fifteen minutes.

She seems well nourished. Her countenance appears somewhat anxious, but that might be due to nervousness on coming before so many strangers. The eyes are a trifle prominent. There seems to be a little cyanosis about the lips, but that may be due to dilatation of the venous capillaries. Where shall we look for the cause of her symptoms—in the heart or lungs? The heart is enlarged, but without any valvular lesions. She has never spat blood, and has never had any pulmonary trou-

[1] A clinical lecture delivered at Bellevue Hospital.

ble, except this shortness of breath. You will notice, on inspection of the chest, aside from the difficulty of breathing, that there is a fulness above the sternum. But she is forty-three years of age, and is pretty stout, and in stout people we often see such fulness, it usually being of no special significance. I have said she has no pulmonary disease, and there is enlargement of the heart, without valvular lesion. What can cause enlargement of the heart without valvular disease? Possible causes are cirrhosis of the liver, contracted kidney, arterial sclerosis, and tumor. Having excluded the first three, how might a tumor bring about this condition? It would probably have to be in the thorax, and near enough to the heart to produce obstruction, as happens in disease at the aortic orifice. The heart has to act with increased force to overcome the obstruction.

We have already determined the presence of some enlargement above the sternum, and on palpation we find a slight pulsation in this region, but this might be present without a coincident lesion in a nervous or anemic person. The transverse portion of the arch of the aorta is near to the finger when palpating in the suprasternal notch. The pulsation felt is not an expansile one. On percussion we find dulness, amounting almost to flatness, at the right of the upper third of the sternum. Auscultation, with the aid of the stethoscope, reveals a roaring sound or hum, which occurs practically with the first sound of the heart. It would not do to puncture the tumor to determine whether it is an aneurism or not. A few years ago a colored man came here with a huge tumor in the upper portion of the thorax. It fluctuated, and a physician had told him to poultice it for another forty-eight hours and he would then open it. The patient entered the hospital with an aneurismal tumor thirteen inches in diameter, the largest on record.

Having determined the presence of the tumor, how are we to know that it is an aneurism? By more careful palpation over the area of thoracic dulness, pressing the fingers between the intercostal spaces, and aiding them further by pressure with the other hand, we find an expansile pulsation in the tumor synchronous with the cardiac systole. The second sound of the heart is very loud and is accentuated. The pulse in the right radial artery is much more feeble than that in the left. While this might occur in connection with any mediastinal tumor, it is so much more likely to be met with in cases of aneurism that it constitutes further evidence in favor of our diagnosis. She has practically no cough. The tumor might press upon the recurrent laryngeal nerve and cause paralysis of the vocal cord, usually of one side only, but in this instance the larynx has been examined, and no paralysis has been found. She has marked diminution of the respiratory murmur, extending down the right side. This condition is not always present in aneurism, but the sign is of value in connection with the others when it is present. There is no specific history in this case, as there is in most cases of thoracic aneurism not due to traumatism. We do find it occasionally in persons with simply a rheumatic or gouty history. Anything that will produce endarteritis may produce aneurism, but syphilis is the most frequent cause.

The patient has an aneurism at the junction of the ascending and transverse portion of the arch of the aorta—the most frequent seat of thoracic aneurism. It is the most frequent seat, probably, because it is at this point that the blood first meets with resistance; it is the first point where it turns the corner after leaving the left ventricle. There are a good many other points of interest in connection with the subject of aneurism, but the one of special interest in this case is that the woman was able to come here and walk up the stairs with such slight discomfort, considering the size of her aneurism.

CASE II.—We have here a patient whose case presents a number of points of interest, but one in particular, to which I wish to call your attention. She came into the hospital about a year ago with an attack of acute articular rheumatism, and along with it evidences of a chronic endocarditis, the result of a former attack of the same disease. There was evidence of lesions at the aortic and mitral orifices, and the heart was very much enlarged, hypertrophy predominating over dilatation. Compensation was ordinarily good. She still has a double lesion at the mitral orifice, as well as a double one at the aortic. Secondary to this, or as a result of the damming back of blood in the pulmonary vessels, she has dilatation of the right ventricle, with tricuspid regurgitation. One would think that was enough, but, in addition, she has a moderately enlarged spleen and a very decidedly enlarged liver, and also gives evidences at times of a passively congested kidney, but all of these are secondary to the cardiac disease. She has also had several attacks of pulmonary edema, and three days ago became very much excited, and had palpitation and evidences of want of heart-compensation. Pulmonary edema developed, and her temperature, in the evening, was found to be as high as the thermometer would register—in other words, 112° F. The house-physician thought there might be some error, and took the temperature again, this time in the rectum, and again it went up to 112° F. Thinking to still further corroborate the observation, he took the temperature with another thermometer, and with the same result. That was three days ago. The next day the temperature was up to 104.6° F., and last night it was 108° F.

The case is of special interest, since we were told a few years ago that a temperature of 108° F. was inconsistent with recovery; yet here is a patient with advanced cardiac disease, and with her viscera passively engorged, who will develop such a degree of temperature and recover from it, notwithstanding all of this crippling of her organs. I am surprised that she can have a temperature of 112° F. and not only survive, but be practically in the same condition as she was before. Cases in which excessively high temperatures have been recorded have been usually in connection with hysterical patients. This patient is to be classed in that category. Some of you may remember that I have cited a case reported by a gentleman of high authority, where the temperature of a male patient rose to 122° F. Another case was reported at a meeting of the Association of American Physicians and Clinicians in which a thermometer was made especially for a patient, the temperature rising to 148° F. In each of these cases

there was an hysterical element. It would seem that in hysterical patients there is a sensitive condition of the heat-centers that, under certain conditions, is conducive to a very high degree of temperature. In this instance nothing was done to lower it, and the patient soon recovered her normal status.

CASE III.—We have here an Italian who was brought to the hospital in a cyanosed condition, and with evidences of consolidation of the upper and middle lobes of the right lung, believed to be pneumonia. He was put to bed at once and given ordinary treatment. The temperature ran high, ranging from 104° to 106° F., and the pulse was dicrotic. On account of the cyanosis the house physician had oxygen administered freely, and, in addition to sustaining treatment, he was given baths. When I saw him I decided to try a plan which I had seen work well before. All treatment was stopped, and cold compresses were applied to the side, extending from the axilla down to the free border of the ribs. Over the compress a towel was placed, and over that oiled silk, the latter for the purpose of keeping the bedclothing dry. The compress was made of a folded sheet, and was dipped in water at a temperature of 70° F. I gave instructions not to hesitate to resort to other means of relief should bad symptoms arise. His temperature began to come down within two hours, the compress being changed every hour during the day, and every two hours at night. The pulse became less frequent, more powerful, and lost its dicrotic character, and he became a great deal brighter; he could sleep, his whole appearance changed, and the cyanotic condition, which had already improved under the oxygen, improved still further. This treatment, by cold compresses alone, was tried somewhat as an experiment. As you know, I am not much of a believer in local applications in pneumonia. It certainly does not seem rational that we can make any applications around the thorax which will directly affect the internal organs. I am inclined to think that as much benefit will come from wrapping the wet cloths around the abdomen, and I have made up my mind to try it. I will make the application to the same amount of surface as upon the thorax, and will see whether the same result will follow. I admit that if there is pain, the putting on of a pretty tight compress will give a certain amount of relief, and the patient can then breathe more deeply, just as would happen if one were to put on strips of adhesive plaster. Simply pinning a cloth tightly around the chest will have some beneficial effect. Of course, the application of cold compresses is simply a modification of the bath treatment. It is more comfortable, and is easier to carry out, and the applications are made oftener.

Vaccination in Great Britain.—The government bills to be introduced in Parliament at its next session will include a measure exempting from vaccination the children of parents who have conscientious objection. Government inspectors are now visiting calf-lymph stations on the Continent to ascertain the best means of preparing and distributing calf-vaccine, the use of which by doctors the government is being strongly urged to make compulsory.

CLINICAL MEMORANDUM.

REPORT OF A CASE OF ANTHRAX CARBUNCLE.

BY M. G. MOORE, M.D.,
OF VINCENNES, IND.

ALTHOUGH the typical anthrax carbuncle is not likely to be confounded with any other affection, diagnosis is apt to be delayed on account of the extreme rarity of the disease in this country. In persons employed in handling wool and hides, the physician is on his guard, and diagnosis is usually made early, but in cases in which the occupation of the patient furnishes no clue, the disease is very likely to get beyond control before its gravity is recognized. We know, however, that the disease does occasionally occur in our country, that early diagnosis is essential to its successful treatment, and that treatment, to be efficient, must be prompt and radical.

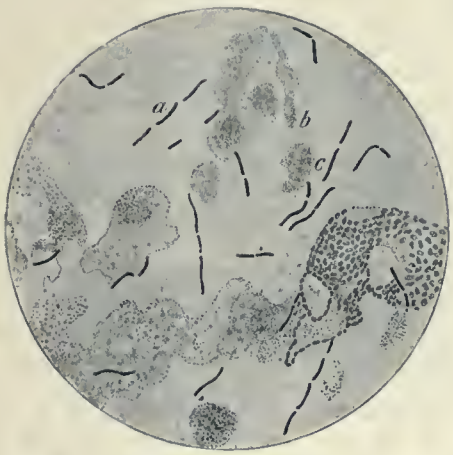
The case which is here reported occurred in a man, aged thirty-nine, proprietor of a livery-stable, and prior to this infection in excellent health. The source of infection is doubtful, though it may be stated that a few days prior to the appearance of the lesion, the patient had spent two days at a sale of Texan horses, and had been among the animals much of the time. It is not known, however, that any of the horses were diseased in any way. Nevertheless, it is possible that an animal may carry the disease without itself being infected, and we may conclude that in this we have the probable source of infection.

On July 13th, there appeared on the patient's face, at the point of the cheek-bone, a minute, dusky-red papule, with burning and itching, out of proportion to the size of the eruption. On the second day, the eruption assumed a vesicular form, the burning and itching being entirely gone. On the third day, the vesicle burst, disclosing a central eschar as large as the end of a lead-pencil. Up to this time there had been no symptoms aside from the local lesion, but on the evening of the third day, the patient experienced marked rigors for about two hours, followed by mild fever, accelerated pulse, headache, and general aching, especially of the limbs. From this time the patient was confined to his room, though able to sit up most of the time. By the fourth day the eschar was enlarged to the size of a penny, presenting a tough, grayish, sloughing surface, from which continually oozed clear serum. An area of induration extended for a considerable distance around the lesion; about a third greater than a silver dollar in circumference, of a decided purplish color, stony, hard, and absolutely painless. Outside of this area of induration there was much swelling, extending to the orbit and the corner of the mouth anteriorly, to the zygoma above, to the ear, and involving the parotid posteriorly, and to the lower border of the jaw below. The enlargement of the parotid was painless, though two small cervical glands just back of the angle of the jaw were enlarged and quite painful on pressure.

On the fifth day of the disease, the eschar was the size of a silver quarter, distinctly umbilicated, and around the margin there developed a secondary ring of small vesicles,

with gradual extension of the tissue-necrosis. During these days the general condition of the patient became steadily worse; complete loss of appetite, feeble and rapid pulse, fever continuing at about 102° F., rising half a degree to a degree in the evening, and on the evening of the sixth day there occurred a well-marked chill, followed by a temperature of 103.8° F., intense headache, and great prostration. The lesion and the general condition of the patient for the succeeding thirty-six hours remained practically unchanged, and until the morning of the ninth day, when the swelling and induration of the infected area began very slowly to subside, and the patient's general condition to improve, though there was slight elevation of temperature to the fourteenth day.

The local treatment consisted of the injection of 30 minims of a seventy-five-per-cent. solution of carbolic acid at various points about the base of the indurated area, as soon as diagnosis was made. The needle was introduced as far as the center of the lesion, and the injection made as it was slowly withdrawn. No toxic



Cover-glass preparation from slough showing (*a*) anthrax bacilli, (*b*) pus-cells with nuclei, and (*c*) free nuclei.
Zeiss' aprochromatic objective, one-twelfth; ocular, six.

symptoms appeared from the carbolic acid. The infected area was frequently cleansed by washing with strong bichlorid of mercury solution, and was kept constantly covered with cloths wet in bichlorid solution 1–500.

The general line of treatment was supportive, consisting of frequent doses of quinin and iron, together with whisky in the form of egg-nog and milk-punch. The administration of strychnia and digitalis was necessary to sustain the action of the heart, which was at all times feeble. The patient made a good recovery, with remarkably little sloughing or scarring, either from the lesion or the carbolic-acid injections. Diagnosis in this case was verified by bacteriological examinations made before radical treatment was begun, and the characteristic bacilli of anthrax were found in a number of preparations.

Cover-glass preparations, stained with methyl blue and mounted in glycerin, were made from the serum which continually oozed from the central eschar, from the semi-purulent contents of the vesicles in the secondary ring, from blood drawn from the margin of the sloughing area, and from the slough itself, the accompanying drawing being made from the latter. In all these preparations, the bacilli of anthrax were found in considerable numbers, being most numerous in the slough, and least so in the blood drawn from the margin of the slough. Examination of blood drawn from within two inches of the base of the indurated area revealed no bacilli, clearly demonstrating an effort on the part of Nature to circumscribe and limit the infection by this wall of indurated tissue; an effort on the success of which depended the life of the patient.

On the third day following the carbolic-acid injections, examinations were made identical with those made at first, and no bacilli were found, proving the efficacy of carbolic acid in the destruction of this, the most tenacious of life of all bacterial organisms. Although the recognition of the spores of anthrax alone in tissue under these circumstances is almost if not quite impossible, it is reasonable to conclude that their destruction was also complete. We may therefore conclude that in carbolic acid, if employed early and in strong solution, we have a safe and efficient means of combating this malignant disease.

MEDICAL PROGRESS.

The Production of Streptococcus-antitoxin by Means of Electricity.—As the result of an experimental investigation conducted at the Institute for Pathological Anatomy of the University of Padua, BONOME and VIOLA (*Centralblatt für Bakteriologie, Parasitenkunde und Infektionskrankheiten*, 1896, Nos. 22, 23, p. 849) have determined that alternating electric currents of high tension are capable of rendering innocuous most virulent cultures of the *Streptococcus-pyogenes*, without modifying the chemic reaction of the cultures or the form of the parasites. The result is brought about even when the current passes but for a short time, and it is constant. The action of the current takes place only upon the fluid portion of the culture, *i. e.*, upon the dissolved toxins rather than upon the streptococcus. The latter, when inoculated upon new media, develops with its previous rapidity, and retains its pathogenic activities. The streptococcus is capable of preserving its vitality for two weeks in the electrified culture. Under the influence of the current the toxins of the streptococcus are converted into antitoxins, just as antitoxins are produced in the bodies of immunized animals. The antitoxins obtained through the electric current from old cultures of the streptococcus possess great activity, being capable of neutralizing outside the body ten times the lethal dose for rabbits. The antitoxins obtained from recent cultures are weak, because these contain only a small amount of toxins capable of conversion into antitoxins. These antitoxins possess active protective and curative properties with regard to streptococcous-infection in rabbits. They behave like true vaccines, and like the vaccine obtained by heating streptococcous-cultures to between 126° and 150° F., are not entirely innocuous for rabbits, producing a progressive marasmus and at first elevation of temperature. The

antitoxins probably act in the rabbit by stimulating the formation of substances capable of destroying the streptococcus outside of the body by causing degeneration of the streptococci.

An Unusual Cause of Lead-poisoning.—At a recent meeting of the Société de Biologie, CHARCOT (*Compt. rend. hebd. de Séances de la Soc. de Biol.*, 1896, No. 22, p. 639) related the case of a woman, thirty-two years old, employed in the manufacture of artificial flowers, who presented characteristic manifestations of lead-poisoning. There had frequently been colic, with obstinate constipation. Careful examination failed to disclose the existence of a blue line at the margin of the gums, but the mouth was well cared for and the teeth were in good condition. The woman was pale and emaciated. On inquiry it was learned that in her occupation she wrapped the stems of artificial flowers with green paper, often wetting her fingers with the tip of her tongue. An analysis of the paper used disclosed the presence of lead in large proportions. The case was used also to illustrate individual susceptibility to lead-poisoning, as the woman knew of none of her associates who were similarly affected.

A Simple but Successful Treatment of Colles' Fracture.—In the *Archiv für klin. Chirurgie*, vol. liii, p. 336, the results of a simple method of treatment of Colles' fracture of the radius, as carried out in the Königsberg Polyclinic, are given by STORP. This treatment is essentially the same as was advocated many years ago by Sir Astley Cooper, *viz.*, the suspension of the arm by the wrist, the hand being allowed to drop sharply to the ulnar side. Storp insists that attention should be directed especially to the complications of a Colles' fracture, and not to the fracture of the radius. In almost any decently applied apparatus the bone unites rapidly and firmly. On the other hand, the complications, such as rents in the joint-capsule, made by splinters of bone, or openings into the posterior or anterior tendon-sheaths, or injury to the triangular ligament or its attachments should be attended to. In all such cases, if the hand remain too long in splints, organization of blood-clots and the formation of adhesions in joint or tendon-sheath delay complete recovery, or possibly permanently disable the hand. To avoid this, the fingers are now almost universally left free, and massage applied at an early date.

Storp has treated 104 patients in this manner: A strip of rubber-plaster, 2½ inches wide, is wound about the arm just above the wrist-joint. A second piece is placed exactly over the first, a fold being made in it on the radial side, which stands out far enough from the arm to allow a large hole to be made in it. Through this hole a string is passed, and the arm is held high up on the chest, the hand dropping downward toward the ulnar side.

The treatment is at first rather painful, but if the arm is kept high up venous congestion is avoided, and the pain becomes much less. The plaster is removed in ten days and the hand simply placed in a sling, while the patient is advised to use it carefully. In a few of Storp's cases, in which there was extensive hemorrhage, massage was employed. The average duration of treatment was three weeks, while fourteen to eighteen days sufficed in patients under twenty years of age.

The results were exceptionally good. Of the ninety-five cases in which directions were carried out, the arms of ninety-one were completely restored in appearance as well as function; in the other four the functional result was a good one, but there was a slight radial deformity in three cases, and a rather marked radial deformity in the fourth.

Ozena and Its Treatment by Electrolysis.—BAYER concludes an interesting article on the cause and best treatment of ozena (*Münch. med. Wochensch.*, No. 33, 1896) as follows:

A. Ozena is a trophoneurosis consisting of (1) an anomalous secretion of the mucous membrane of the nose, naso-pharynx, and pharynx, whose product serves as a culture medium for a microbe peculiar to ozena, and producing the odor so characteristic of that disease; (2) a disturbance of nutrition, with atrophy of the mucous membrane; (3) a rhinitis, usually at first hypertrophic, which is brought about by the irritation of the secretory products, these acting as foreign bodies. *B.* The best, one might say the specific, treatment of ozena is by electrolysis, which, however, is not absolutely free from danger.

Bayer insists on absolute cleanliness. The careful removal of all crusts and the frequent use of nasal douches of lukewarm water, or mild antiseptic solutions, precede the application of electricity. The positive pole, a copper electrode, is introduced into the nose, and by means of a relatively weak current and oft-repeated treatment, this obstinate disease may be completely cured. He prefers a weak current as being safer than a stronger one, but its therapeutic action is slower.

The action of the electricity is threefold. First, the oxychlorid of copper is set free into the tissues and produces chemical effects there. Secondly, the electric current has been asserted by some to be an active germicide. Thirdly, and upon this the author lays especial weight, by the "deep molecular disturbance," which the current brings about, the nerve-endings are affected, and as a result a trophoneurotic reflex-action is produced, more blood flows to the mucous membrane, the excretion becomes more fluid, and no longer furnishes a medium for the growth of the ozena-microbes. Be the theory as it may, the results of this treatment were in every way satisfactory.

Treatment of Simple Ulcer of the Stomach.—At the recent Congress of Physicians at Hamburg (*Berlin. klin. Woch.*, November 2. 1896), RATJEN expressed himself as dissatisfied with the usual treatment for ulcer of the stomach, such as rest in bed, hot poultices, fluid diet, and bismuth subnitrate and morphin, on the ground that the benefit thus obtained is more apparent than real, and that relapses often occur. He therefore advocates rectal feeding. For about ten days nothing but a little water or bits of ice, or weak brandy and water, is given by the mouth. The patient is kept in bed and poultices are applied. Under these conditions he believes that the shrinking of the stomach and the diminution of its motions, and

the lessening of the secretion of hydrochloric acid favor the rapid cicatrization of the ulcer.

Bimanual Examination of the Bladder.—HENRY MORRIS emphasizes in the *Lancet*, October 31, 1896, the diagnostic value of bimanual examination of the bladder under ether. Naturally, such examination can be more perfectly carried out in the female than in the male, but as digital exploration of the female bladder is a still more satisfactory, and yet entirely safe procedure, it is in the male that bimanual palpation finds its chief place, and especially in those cases where, on account of hemorrhage, a satisfactory systoscopic examination is not possible.

Morris cites three cases, two of papilloma and one of an ulcerated cancer of the bladder, in which, under an anesthetic, with one finger in the rectum and the other hand pressing the previously emptied bladder into the pelvis, he was enabled to make a correct diagnosis. The cancer felt like a small, hard, flat mass about the prostate and a little to one side. The papilloma had a spongy feel. Suprapubic cystotomy was performed in each case. In not one of the three cases had Morris been able to make out anything abnormal by rectal examination alone without anesthesia.

The Bacteriotherapy of Malignant Tumors.—As the outcome of rather extended clinical observation in the surgical clinic of the University of Heidelberg of the result secured in the treatment of inoperable malignant neoplasms with the toxins or with the antidotal serum of the *Streptococcus pyogenes* and the *Bacillus prodigiosus*, PETERSEN (*Archiv. für klin. Chir.*, B. liii, H. 1, p. 184) has arrived at the conclusion that in the treatment of carcinomata either of the methods is entirely without promise, while in the treatment of sarcomata success is only exceptional. Against this slight and dubious advantage must be placed the dangers of intoxication, as well as those of stimulation of the new growth to increased activity.

THERAPEUTIC NOTES.

Dysmenorrhea with Menorrhagia.

℞ Tr. hydrastis canaden. } aa . grm. xv (℥ iv)
Tr. viburnum prunifol. }
M. and sig. 10 drops every two hours, in sweetened water. HUCHARD.

Phthisis Pulmonalis.

℞ Iodoform } aa . . . grm. v (gr. lxxv)
Creosote }
Turpentine } aa . . grm. ii (gr. xxx)
Ac. benzoic }
Powd. marshmallow } aa . grm. vi (℥ iss)
Magnesia }
Make 100 pills; 4 to 10 a day. LEGROUX.

For Leprosy, BROCQ is in the habit of administering oil of chaulmoogra, internally. Five drops are given morning and evening, as a commencing dose, either before or after eating. The dose and frequency of taking is gradually increased until the patient is taking from 120 to 200 drops a day, usually in four doses. This large quantity is continued for three days, and excellent results are said to follow its use. The oil may be given in hot tea or coffee, in an infusion of peppermint, in capsules, or in unleavened bread.

Treatment of Acute Tonsillitis.—The following plan of procedure is recommended by GRASSET (*Gaz. hebdom. de Med. et de Chirurgie*, 1896, No. 66) in the treatment of acute tonsillitis:

Milk is given every two hours, day and night.

Every two hours a teaspoonful of the following mixture is to be administered:

℞ Potassium chlorate . . 16 grains
Water . . . . . 1 fluid ounce

During the day the throat should be gargled frequently with a hot infusion, or with the following combination:

℞ Sodium naphtholate . . 5 grains
Cocain hydrochlorate . . 1½ grains
Sirup . . . . . 1 fluid ounce

The throat should be painted three or four times during the day with

℞ Glycerin . . . . 4½ grains
Borax . . . . . 1 dram

If the local condition should become alarming silver nitrate, 1–10, should be applied topically, and the throat sprayed with carbolized water or a solution of phenosalyl, 1–100. If the pain is severe, especially on deglutition, the throat should be painted three or four times a day with

℞ Cocain hydrochlorate . . 8 grains
Glycerin . . . . 1 fluid ounce

The treatment may be begun with ipecac if this drug have not already been given. The patient should be isolated and separated, especially from children and those susceptible to tonsillitis.

The latter may receive by spray, morning and night, two fluidrams of the following solution:

℞ Cocain hydrochlorate } each . 7½ grains
Carbolic acid }
Glycerin . . . . 6 fluidrams
Water, sufficient to make . 1 pint

Or the throat may be painted daily with

℞ Tincture of iodin } . . equal parts
Glycerin }

By the mouth sulphur and arsenic are alternated from month to month. For twenty days a half-glass of some sulphurous water is taken each morning on an empty stomach. This is also used as a gargle. The patient then rests for ten days. At the expiration of this time he takes twice daily, for the next twenty days, a tablespoonful of

℞ Sodium arsenate . . . 1½ grains
Distilled water . . . 10 fluid ounces

Then again the patient rests for ten days, and the alternation is thus kept up. Tobacco and alcohol are to be abstained from. Chilling, and association with cases of tonsillitis are to be avoided. If possible, a visit should be made annually to some sulphur resort. In case of frequent recurrence of attacks, recourse should be had to the galvano-cautery, or amygdalotomy, according to the size of the tonsils.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

DIPHTHERIA-ANTITOXIN — INVESTIGATION BY THE MEDICAL NEWS.

As a purely scientific enterprise, the MEDICAL NEWS has undertaken during the past few months an investigation to determine the quality of the diphtheria-antitoxin that was being supplied to physicians in different parts of the country. The results of the investigation are set forth in this issue of the NEWS.

What position antitoxin shall occupy as a therapeutic agent is the great question of the hour. Statistics have been gathered and collective investigations have been undertaken to settle it. The fact must be recognized, however, that the value of these statistics rests primarily upon the quality of the serum used. In undertaking this investigation, therefore, the NEWS felt that it was laying hold of the very root of the matter. And out of this was to come an explanation of the great diversity of results experienced by different practitioners. In this we were not mistaken, as the accompanying report conclusively shows. Indeed, the prominent fact brought out by the investigation is the striking irregularity exhibited by the different preparations. Two or three of the samples were so feeble in antitoxic properties that they were practically worthless for therapeutic purposes. More of them however contained greater antitoxic properties than fell below the strength stated upon the label. But for statistical purposes, and as a basis upon which to establish a system of accurate dosage, this is certainly to be deprecated. In determining also how great a part the antitoxin plays in producing unfortunate sequelæ this variation in strength renders statistics utterly void. It is also of interest to note that in some of the samples the strength of the antitoxin was not given upon the labels, so that the physician was necessarily in the dark regarding the strength of the preparation he was using.

One of the most difficult problems in connection with serum-therapy from the onset has been the question of accurate dosage. If to the lack of knowledge regarding the amount required by the patient, uncertainty as to the strength of the antitoxin used must be added, the general practitioner will be hopelessly confused. This, however, is not a necessary condition nor need it be a permanent one, although it now adds greatly to the difficulties that exist in the practical application of this remedy.

It is well known that serum drawn from different horses varies greatly in its antitoxic properties, and it is only by the greatest care that the strength of the serum can be accurately ascertained. Each lot must be tested for itself. It is probably in this department of the work that carelessness has existed. These tests must be made by one of great experience and with great care, otherwise they are of little value. The profession can justly demand that each and every package of serum sent out of a laboratory shall not only bear the personal guarantee of an expert, but that this shall be something more than a formality.

It should be understood by the manufacturers of antitoxin that what the medical profession wants is not a cheap product, but one that is absolutely reliable. Every one knows that to produce a standard antitoxin there is required expert knowledge, the expenditure of a considerable amount of time, and the greatest care. All of these naturally increase the cost of the remedy; but the physician and the public will cheerfully bear such expense if they can be certain of the quality of the article.

How the present condition is to be remedied in a country like ours, where there are no governmental

restrictions whatever upon the manufacture and sale of products like antitoxin, is difficult to say. The only means which the average physician has of knowing what is being furnished him in the way of antitoxin, is by just such an investigation as this which the NEWS has inaugurated, and it is our purpose to repeat this from time to time, and give our readers the benefit of it.

So many sources of error exist in the method now employed for testing serum, that unless they can be eliminated some new method must be devised. It has recently been discovered that under the influence of the electric current the toxins of the streptococcus are converted into antitoxins. Is it not possible that out of some such suggestion a method of determining the strength of serum by this wonderful agent may be devised?

The well-known ability and professional standing of Dr. Abbott are a sufficient guarantee that the work assigned to him in this investigation has been done with care and thoroughness, and the thanks of the NEWS are due him for the scientific manner in which he has performed his task. The editor also desires to express his appreciation of the generous spirit shown by the publishers, Messrs. Lea Bros. & Co., in making possible this investigation, and the cordial support he has received at their hands throughout its entire prosecution.

THE PASSING OF THE PHYSICIAN.

IT needs no prophetic eye to see the extinction awaiting the practicing physician, using the term in contradistinction to the hospital or dispensary physician. Surgeons, aside from professors and hospital and dispensary surgeons, are already extinct. The drag-nets of ambulance, dispensary, clinic, and hospital, have secured such a "corner" in surgery that no man outside the chosen few can make a living.

What has occurred in surgery is now occurring in medicine. No patient able to walk or ride in a cab need pay a cent for medicine or treatment. If slightly hesitating on the brink, the mælstrom of dispensary, clinic, or hospital, will suck him into its hungry and capacious maw, from which nothing is ever vomited back but statistics. If too sick to walk or ride in a cab, an ambulance waits to carry him tenderly, and without shock or exposure, to sumptuous hospital apartments, built possibly by misused funds donated to the hospital for charity. Ambulating and portable sick people being thus provided for, there remains only a small class of the desperately sick whose removal might mean death. To provide for these cases it is only necessary to slightly enlarge the staff of out-door visiting physicians already attached to our dispensaries and hospitals, and *Presto!* the thing is done! And the weary and struggling outside general practitioner can go home, shut himself up with his emaciated wife and starving children, and turn on the unlighted gas.

These words are not written in jest, but embody the sober thoughts of one who has for twenty years watched the growth, abuse, and degradation of medical charity, hand in hand with which have increased the hardships of the general profession. Let the incredulous glance at a few figures.[1] In the year 1893, 75,094 patients were treated in the hospitals of New York City; during the same year 680,789 patients were treated at clinics, dispensaries, and out-patient hospitals. If we make a liberal allowance for reduplication, there will still remain a stupendous and staggering array of figures.

In the same year there were in the city 2842 "regular" practitioners of medicine. The number of "Homeopaths," Eclectics, "root and herbs," and quacks, was not obtainable, but it probably nearly equaled the list in the "Medical Register." Putting a very liberal estimate upon the number of people trying to get a living out of the pursuit of medicine, they numbered in that year probably 4000 souls. The population of the city was about 1,800,000, which would give each medical man or woman a *clientèle* of about 450, *provided* an equal distribution was made. Such, however, has not been the case. The professors, and the hospital and dispensary physicians get about one-half, the clinic, the hospital, and the dispensary the other half, and the struggling outsider gets the rest.

The remedy? None is available. Experience has repeatedly shown us that *unanimous* and *persistent* action on the part of doctors is impossible. Let a board of governors of any hospital or dispensary dismiss its attending staff because of a meek and proper assertion of rights, and however flagrant and arbitrary the action, other doctors will fall over each

---

[1] The statistics of Dr. Landon Carter Gray in the recent issue of the MEDICAL NEWS are more recent than these, and confirm the belief that the condition is growing worse.

other in their haste to thrust their necks into the apparently welcome yoke.

The average doctor is servile and shortsighted to an extraordinary degree, bent not only upon his own destruction, but also upon endangering the entire fabric of a noble and benevolent profession. Even plumbers and members of other trade-unions protect themselves by curtailing apprenticeship and by keeping out ignorant cut-throats. Why shouldn't doctors? But it is too late! Even now as we near the vortex of muddy competition, and as we are about to go down for the last time, we must acknowledge a bitter justice in our fate; for years of neutrality and final servility have taught pompous laymen, who pose as public benefactors and philanthropists, that doctors will stand any amount of robbery and degradation to secure and keep a hospital or dispensary position.

THE FUNCTION OF THE PITUITARY BODY.

THERE is always a special fascination about endeavors to penetrate into hitherto unknown territory. Whether it be Darkest Africa, the deepest recesses of the thyroid, or the innermost stroma of the adrenals, its very mystery lends a charm to the investigation. Ten or fifteen years ago, the three sphinxes whose riddles the anatomist-physiologist needs must answer were the tonsil, the thyroid, and the spleen. Their massive fronts have, however, been attacked with such vigor and effect that the first two can scarcely be said to be puzzles any longer, while the third is pretty certainly known to be either the cradle or the grave of the red blood-cells, and is probably both. The researches and dramatically fascinating discoveries of Metschnikoff have prepared us to appreciate the value of the tonsils as breeders of leucocytes, to "health-officer" the upper part of the alimentary tract after the fashion of Peyer's patches in the lower. This also beautifully explains the frequency and certainty with which they are to be found in the very front rank of every brush with the enemy in these regions, especially if he happens to be that Apache of the sewers, the Klebs-Loeffler bacillus.

The discovery of the possession of protective, trophic, and other similar properties by the blood-serum, and the recognition of the nature of myxedema and goiter, together have led us to understand the thyroid as the great "organizer" of the body-tissues. Through its metabolic action upon the blood-plasma, it keeps all the tissues constantly stimulated to their highest pitch of effort, and prevents their relapsing to the embryonic or myxoid state, which they promptly proceed to do when its influence is withdrawn. Myxedema would appear to be a reversion of the fixed tissues to the ameboid stage.

But we need not, like Alexander, sigh for more worlds to conquer, for another Africa has already loudly challenged the attention of biological explorers—the so-called pituitary body, or *hypophysis cerebri*. Here is absolutely virgin soil for the physiologist. Until within the last ten years, no suggestion even of its function had been made, save the infantile one embodied in the absurd name it bears—that it secreted the nasal mucus, although its sister enlargement higher up in the same tract, the pineal gland, had been thought worthy by Descartes to be selected as the anatomical home of the soul.

As a rule, the true pioneer of medical progress is the clinician, and not the laboratory worker. The first ray of light in this region came from pathology, and not from anatomy or biology. When Souza-Leite announced in 1890 that the pituitary body was markedly enlarged in most cases of the disease described and named by Pierre Marie and himself several years before as acromegaly, he first gave a standing to the question at the head of this article. Hitherto the gland had been almost unanimously regarded as a purely vestigial structure of most interesting and puzzling origin and history, but of no present value whatever to the organism.

For some time after this report, even the majority of pathologists seemed inclined to regard its enlargement as a mere coincidence, or, at most, one of the symptoms of the disease, but when, in 1892, Tamburrini, Brissaud, and Taruffi almost simultaneously reported a similar condition in certain cases of gigantism, this position was no longer tenable. And when it was further shown on the one hand by microscopic examination that the enlargement was a true hypertrophy of the gland substance, and not a mere interstitial or adventitious outgrowth; and, on the other, that in at least three cases marked involvement of the body by neoplasms produced no acromegalic symptoms whatever; and, finally, in 1895, that extirpation of the pituitary in young kittens and puppies was promptly followed by muscular weak-

ness, falling temperature, marasmus, and death; the possibility that the gland still exerted an active influence upon the metabolism of the body was raised to the rank of a high probability. As to the nature of this influence, we are almost completely in the dark, except that it appears to be exerted through the medium of an "internal secretion," like that of the thyroid, which acts chiefly upon the trophic fibers of the peripheral nervous system. The attention of neurologists in particular and of clinicians in general having been fairly aroused, new facts bearing upon the problem began to be contributed from every hand. Cases of fatal acromegaly in giants were reported by Virchow, Dana, the writer, and others. At the same time the skeletons of giants preserved in museums were investigated, that of the celebrated "Irish Giant," Cornelius McGrath, was shown in a masterly and elaborate monograph by Cunningham to present unmistakable traces of acromegaly, including a huge pituitary fossa, while a similar condition was reported from Reggio by Taruffi in the skeleton of a giant who had died in 1808. The records of giants for two hundred years back have been carefully examined, and a number of living ones have been studied, with the result that it is safe to say that from forty to sixty per cent. of these huge creatures are undoubted cases of acromegaly. While from the fact that, out of over one hundred cases on record, only one lived to old age, very few to middle life, and a majority died before the age of thirty, and that many deaths were due to a general failure of the vital powers or some trivial intercurrent disease imposed upon this, it is reasonable to conclude that eighty per cent. of giants are the subjects either of acromegaly or some closely allied trophic disorder. Myth and popular impression to the contrary notwithstanding, giants are a short-lived, feeble-minded, weak-bodied race, shambling in their movements, and of the mildest of dispositions. They are occasionally possessed of great muscular power, but this seldom lasts more than a few years, just as is also seen in some cases of acromegaly. The position which appears to us best to harmonize these facts is that acromegaly and gigantism are similar, if not identical, disturbances of pituitary metabolism, the one beginning in early life before the full stature has been reached, and producing comparatively symmetrical results extending over a considerable period, the other developing after maturity and expending its "overgrowth" force at the points of least resistance to growth—the hands, feet, nose, and lower jaw. In both, the essential process is a more or less rapid overgrowth, reaching a definite limit and soon followed by correspondingly rapid decay. The ultimate result is the same in both, the situation of the outgrowth (extremities and distal portions of appendicular skeleton generally) is strikingly similar; there is the same disturbance of the sexual functions, in fact, almost the only differences between them are in the pressure-symptoms (headache, hemianopia) and more rapid course of the adult form.

WOODS HUTCHINSON, M.D.

ECHOES AND NEWS.

An Appropriation for Examining Surgeons.—The present House of Representatives has passed the pension appropriation bill, which includes the handsome sum of $700,000 for the fees of examining surgeons during the fiscal year.

Statistics of Suicides.—M. Pawloski states that Europe furnishes 25,000 suicides annually. Last year there were 8226 in France alone. The largest percentage of deaths from this cause occurs between the ages of fifty and sixty years.

Mount Vernon Hospital Reopened.—A number of physicians in Mount Vernon, N. Y., have practically decided to reopen the local hospital, which had been closed from lack of funds. January 1st is spoken of as the date for beginning the work anew. Patients without means are to be treated free of charge.

Substantial Sympathy.—The sympathy felt for Dr. Cullingworth by the profession has been shown in a very practical manner. A fund to assist him in defraying the heavy expenses of his recent trial has been established, and the prompt contributions are strong evidences of the interest taken in his vindication. Within the first forty-eight hours over £500 were subscribed.

Death of Dr. Déclat.—In the death of Dr. Déclat, France has lost one of her most distinguished surgeons. He was the author of several treatises on antiseptic methods of treatment, and his name is closely associated with the advocacy of carbolic acid in surgery. After a long and successful professional career in Paris Dr. Déclat retired to Nice, where his death recently occurred.

Increased Salaries.—The Lunacy Commissioners of New York, in accordance with the provisions of the last Legislature, have experienced the pleasant sensation of having their salaries advanced between thirty and forty per cent. In future their entire time will be occupied with the duties pertaining to their offices. Civil-service

methods will hereafter be employed by them in certain departments under their control.

The Question of Medical Bulletins.—The *Medical Press and Circular* commends with highest praise the course pursued by Mr. Herbert Allingham and Dr. Scott in withholding information from reporters of the lay press, regarding the operation recently performed upon Dr. Jameson, when urgent means were used to induce them to comply with this feature of modern journalism. A number of days elapsed before it was generally known who had performed the operation, so carefully did these gentlemen guard their secret. This example of true professional modesty is recommended with special emphasis to the attention of the American profession, among whom a lamentable tendency to use the demands of public curiosity as an excuse for advertising themselves upon unnecessary bulletin boards is frequently observed.

Obituary.—Dr. Leonard J. Sanford, one of the most eminent physicians of Connecticut and a professor in the medical department of Yale University, died at New Haven, December 1st. He had been seriously ill for about two weeks with heart trouble, which perplexed the attending physicians and the patient himself, who watched with professional interest his symptoms and his condition from time to time. Dr. Sanford was born in New Haven on November 8, 1833. He obtained his education largely in his native city, but was graduated from the Jefferson Medical College at Philadelphia in March, 1854. He received the honorary degree of M.A. from Yale in July, 1858, and was appointed professor of anatomy and physiology at Yale in May, 1863. Since that time he had given an annual course of lectures on these subjects, and also upon the subject of hygiene in the medical and other departments of the university. Since 1855 he had been a practising physician in New Haven.

The New Operating Building at the Boston City Hospital.—The new surgical operating building of the Boston City Hospital is finished, and the surgical operating service has been transferred from the old building to the new. The first operation was performed here Thanksgiving Day by Dr. David W. Cheever, senior visiting surgeon, in the presence of the surgical, visiting, and house staffs. While giving some reminiscences in connection with the hospital which were of interest to those who are now or have been connected with it, Dr. Cheever remarked: "Anesthesia, clinical instruction, and asepsis would seem to mark the three epochs of our hospital, and I often wonder, inasmuch as thirty years have brought to pass all these improvements, what surgery will be thirty years hence. It seems to me it has reached its largest limit of operations, and that operations henceforward will probably decrease, because I think that the progress of bacteriology will enable us to prevent a good many diseases, and will anticipate the surgeon by curing cases before they reach his hands."—*Boston Med. and Surg. Journ.*

Bacterial Diagnostic Work in London will Retrograde.—On January 1, 1897, the laboratory work for diagnostic purposes in diphtheria of the London Asylums Board will be discontinued. Whatever examinations of that kind that may thereafter be made will be conducted by the medical men of the several hospitals. The laboratory of the Royal Colleges, that has been the scene of the good work of the past two years for the benefit of the public, will be abandoned by the Board, and the services of Dr. Sims Woodhead will cease in the direction of diphtherial work. The *Lancet* opines that the Board, in taking this backward step, has not been actuated by any preëminent desire for the welfare of the community, and expresses disappointment that the work done in 1896 cannot be extended and amplified to something like the scale upon which the like work is carried on in the United States and in certain parts of the Continent. It further hints that there has been some clashing of interests between the Board and the Royal Colleges, which might better have been placated or overborne on behalf of the suffering general public.

The Tallerman-Sheffield Hot-air Apparatus.—An opportunity was afforded the members of the medical profession to witness the first public demonstration of the Tallerman-Sheffield Patent Localized Hot-air Apparatus at the Hospital for Ruptured and Crippled, New York, December 7th. A number of prominent general practitioners and specialists were present, and after a short introductory by Dr. Gibney, in which he referred to the several cases experimented on in the hospital during the preceding week, the inventor, an Englishman, Mr. Tallerman—a retired merchant (?)—endeavored to describe, in a manner not eminently scientific, the mechanism of the apparatus. Two patients, an acute knee-joint case and a case of chronic sciatica, were put in the machines and kept there for a period of forty to fifty minutes at a temperature of 220° to 240° F. The body temperature was but slightly raised, and very little was really accomplished by the treatment, though much has been claimed for it as a pain-relieving agent. Dr. Gibney, however, showed some children who had been slightly benefited by the repeated "sittings," and while the apparatus bears an English name it is practically an old method—dry heat followed by gentle massage locally—which many doctors have employed for years. On the whole the demonstration was rather disappointing, but some fair results are claimed for it in England in cases of acute rheumatism, lumbago, and neuralgia.

The League Island Navy Yard.—The exposure made by the NEWS, after a careful investigation of the quarters provided for the men at the League Island Navy Yard has been instrumental in calling the attention of the officials to the cause of the unhygienic and insanitary surroundings which exist there. The recent annual report of the post-surgeon, Dr. Wm. H. Rush, to the Navy Department affirms the worst statements made by the NEWS regarding these conditions, and confirms the assurance that the source of disease and contagion could not be ascribed to the Philadelphia water. He says: "There is no sufficient water-supply at this yard. At present, for drinking and cooking purposes, rainwater is used, and in seasons of little rain great economy is required in its use."

For flushing and other cleaning purposes, Delaware River water is supplied. The latter is daily pumped into a large tank in the attics of the houses. The tanks are wooden, unlined, and leak at the joints, and are intentionally overflowed in order to fill an iron tank alongside of the houses used for outdoor purposes, so that in the large leaden troughs under the tanks there is more or less water evaporated, augmenting that from the exposed surface of the tanks. Two cases of sickness have originated in one of the houses, which I attribute to this source. One case developed into typhoid fever. Inquiry and rumor have shown the existence of diarrheal affections among the workmen employed on the pumps along the river front, who are compelled to use the rainwater for all purposes. Cases of typhoid fever have developed among them."

SPECIAL ARTICLE.

THE QUALITY OF ANTITOXIN USED IN AMERICA.

AN INVESTIGATION BY THE MEDICAL NEWS, EMBRACING THE RESULTS OF CAREFUL TESTS APPLIED TO THE SAMPLES OF THE LEADING MANUFACTURERS, INCLUDING MUNICIPALITIES AND PRIVATE ENTERPRISES.

THE most important contribution that has been made to the subject of serum-therapeutics, especially in its application to diphtheria, was the Report[1] of the Collective Investigation Committee of the American Pediatric Society, which appeared last summer. This report was awaited with unusual interest, and proved a great surprise to the friends, as well as to the opponents, of serum-therapy. One of the most striking features developed by the investigation was the widespread employment of the antitoxin, and the number of physicians who were using it. The general inference to be drawn from the report, as a whole, was that the antitoxin treatment of diphtheria had proved so efficient that there was no longer any doubt of its permanency as a therapeutic measure; and yet every one who carefully analyzed its details was possessed of the conviction that it bore two pronounced elements of uncertainty. The first had reference to the amount of the dose, and the second, which is still more important, was a doubt as to the quality of the serum. When over six hundred physicians in private practice are making use of a therapeutic agent, the quality of that agent is of the supremest importance.

It therefore occurred to the MEDICAL NEWS that an investigation into the quality of the various serums most extensively used in the large cities of the country, would be a fitting supplement to the Collective Investigation Report, and would render to the cause of serum-therapy, to the army of physicians who were making use of this agent, and, indeed, to humanity at large the greatest possible service.

[1] See MEDICAL NEWS, July 4th, 1896.

METHODS OF SECURING SAMPLES.

In order that the investigation might be conducted with absolute impartiality, samples of antitoxin were procured in the open markets in accordance with the method adopted by any physician intending to use the remedy in his private practice. These samples were supplied by doctors residing in different localities, with the understanding that each should procure the brand of serum most extensively used in his respective city. Nineteen specimens were thus obtained; six of these were the output of two municipal laboratories, *i.e.*, they were board-of-health serums of New York and Philadelphia. The products in each case bore duplicate labels, except as to the dates of manufacture. Thirteen came from private manufacturers in this country and abroad, representing the following firms: Institute Pasteur de Lille, Schering, Parke, Davis & Co., Institute Pasteur of Paris, H. K. Mulford Co., Buffalo Antitoxic Co., Roux Institute Pasteur of Paris, Behring, and the New York Pasteur Institute (Gibier). These were procured from the following cities: Montreal, New York, Philadelphia, New Orleans, Buffalo, and Cleveland. The serum issued by the Board of Health in Chicago is the product of the laboratory of the New York Board of Health, and, therefore, no samples from that city were examined. No serum was secured from Boston, the Massachusetts State Board of Health, when appealed to, deciding "not to submit a sample for the reason that the antitoxin is not for sale, and that all necessary questions relating to it are published in the reports of the board when ripe for it."

It is therefore evident that the work was undertaken without the possibility of favoritism or prejudice, and that the specimens were procured under conditions corresponding as closely as possible with those met by the practitioner when called upon to obtain it for immediate administration.

HOW THE SAMPLES WERE PREPARED FOR THE TEST.

The samples were sent direct to the New York office of the MEDICAL NEWS. Upon their arrival the external wrappers, and the labels on the bottles were carefully removed, pasted in a book, and numbered 1, 2, 3, etc., the corresponding figures being pasted upon the bottles, so that there remained no means of identifying them except by the number attached. These bottles were then forwarded to Professor A. C. Abbott at the Laboratory of Hygiene, University of Pennsylvania, at Philadelphia.

In obtaining the service of so distinguished a bacteriologist as Dr. Abbott, we feel that the most perfect confidence in the scientific accuracy of this report is secured.

That our readers may have a definite idea of the

procedure followed in testing these samples, we preface Dr. Abbott's report with the following explanation:

METHOD OF TESTING A SAMPLE OF ANTITOXIN OF UNKNOWN STRENGTH.

First, a guinea-pig weighing about 250 grams is injected with the amount of toxin which we know from previous experience to be probably the fatal dose. Six other guinea-pigs are then described and weighed. Into each of six separate flasks is placed ten times the amount of toxin injected into the original or control-pig. The problem is to determine how much of the preparation of antitoxic serum to be tested will protect a 250-gram pig from ten times the fatal dose of toxin. We therefore mix with the toxin in each one of these six flasks different amounts of antitoxin, beginning with No. 1, an amount of antitoxin so large that we feel sure that if any antitoxin whatever is present in the serum, it will save the life of the guinea-pig into which it shall be injected; and No. 6 receiving an amount of serum so small that we feel sure that it will probably contain an insufficient amount of antitoxin to protect the guinea-pig into which it shall be injected. The other four guinea-pigs will receive amounts of serum varying between these two limits. If now we find, for instance, that pigs which received $\frac{1}{100}$ of a c.cm. of a serum and larger quantities live, and those receiving smaller quantities die, we know that $\frac{1}{100}$ of a c.cm. was sufficient to protect the life of the guinea-pig from the fatal effects of ten times the mortal dose of toxin. That is, this serum contains ten or more units of antitoxin in each c.cm. If now the pig shall receive the next smaller dose of antitoxin ($\frac{1}{200}$ of a c.cm. of antitoxin) and die, we know from this first experiment that this antitoxin contained more than ten units and less than twenty units in each c.cm. If we wish to test the serum accurately, we would now take a new batch of five guinea-pigs, giving one a dose of toxin which a week before proved to be the fatal dose; describing and weighing again the other four pigs, we would add to each of the four flasks a quantity of toxin ten times the amount fatal to the 250-gram guinea-pig, and add to the toxin in flask No. 1, $\frac{1}{120}$ of a c.cm. of serum; to flask No. 2, $\frac{1}{140}$; to flask No. 3, $\frac{1}{160}$; to flask No. 4, $\frac{1}{180}$. If now we find that the guinea-pig receiving $\frac{1}{140}$ of a c.cm. of serum lives, and the pig receiving $\frac{1}{160}$ dies, we know that this serum contains between fourteen and sixteen units in each c.cm. This would be as accurately measured as would ever be necessary. In both these experiments it is understood that the control-pig, that is, the pig receiving the supposed fatal dose of toxin, died from the toxin within three weeks of the date of the injection.

BACTERIOLOGICAL REPORT[1] OF A. C. ABBOTT, M.D. (PROFESSOR OF HYGIENE IN THE UNIVERSITY OF PENNSYLVANIA), AND O. P. PHILLIPS, PH.M. (THOMAS SCOTT FELLOW OF HYGIENE, UNIVERSITY OF PENNSYLVANIA).

DURING the early autumn of the present year we received a communication from the Editor of the MEDICAL NEWS calling attention to the discrepancy that is observed in the results of the therapeutic use of diphtheria antitoxin in this country, and suggesting the possibility of this being due to lack of uniformity in the strengths of the various preparations for sale by American dealers. He requested us to undertake the testing of samples of serums from the different makers from whom our supplies are obtained. This we consented to do on the conditions that the samples be obtained by him, or by an agent, in the open market, without the dealers' knowledge of the use to which they were to be put; that the labels be removed, the bottles be designated by a number, and shipped to this laboratory, a careful record being kept by the Editor of the NEWS as to the identity of the numbered bottles. This precaution we thought wise, in order to eliminate any prejudices on our part in favor of, or opposed to, serums from particular sources.

The results of our investigations, that are here presented in tabulated form, refer to the serums by number, in the order that they came into our hands. We are not aware of their source in a single instance. The interpretation of the numbers by which we designate the serums will be appended to this article by the Editor of the MEDICAL NEWS, for whom these tests were made.

The method employed in determining the antitoxic values of the several samples is that of Ehrlich, Kossel, and Wassermann, and the protective values of the serums are expressed in terms corresponding to their standard, *viz.*, a serum of such strength that one-tenth c.cm. fully protects a guinea-pig against ten times the minimum fatal dose of diphtheria toxin is a "normal serum," and one cubic centimeter of such a serum contains an "immunizing unit." Serums of such strength, therefore, that 0.01 and 0.001 c.cm., have the same effect as 0.1 c.cm. of a normal serum, are ten and one hundred times as strong as a normal serum, *i.e.*, contain ten and one hundred immunizing units respectively per c.c.m.

On this basis, nineteen different samples have been tested by us, with the results given in Table I.

From a perusal of this table, it will be seen that the majority of the samples exhibit the average required strength; that several, *viz.*, Nos. 1, 2, 7, 14, were unusually rich in protective substances, while

[1] From the Laboratory of Hygiene, University of Pennsylvania.

in only a very few samples, Nos. 9, 11, 15, was there a relative deficiency of antitoxic properties.

In one or two instances the figures given for the value of a sample do not, in all probability, represent the *highest* limit of protection possessed by these

TABLE I.

Serum number.	Times tested.	Immunizing units per c.cm.	No. of c.cm. of serum in original flask.	Total No. of immunizing units each flask.

serums; this refers only to those samples that proved to be of unusual strength. On the other hand, the samples shown to be so poor in antitoxin as to represent but a very low multiple of a normal serum, were eliminated after tests that to us demonstrated their comparative uselessness for therapeutic purposes. The figures given for the balance are those at which protection was absolute.

This closes Dr. Abbott's report.

In order that a comparison may be made between the actual strength of the various samples as shown above and the advertised strength as indicated on the labels, we append Table II.

[1] The serum in flask No. 4 was exhausted before this test could be carried higher.

A comparison of this table with the preceding one shows a very great discrepancy in some instances in the actual strength of the sample and its advertised strength. Not only that, but samples from the same manufacturer purchased in different markets at the same and different dates show a wide variation. For instance, samples Nos. 1 and 4 both came from one laboratory and were procured at the same time; samples Nos. 5 and 6 came from one laboratory at one time and bore the same date; samples Nos. 9, 11 and 14 all came from one laboratory. Nos. 9 and 11 were purchased in New Orleans and No. 14 in Cleveland. Nos. 13 and 19 came from one laboratory also.

CAUSES OF VARIATION AFTER SERUM HAS BEEN TESTED AND BOTTLED.

Practically it may be said that some samples of serum are found to retain their strength absolutely for periods of from three to twelve months. Other samples are found to gradually lose their strength, so that at the end of three or six months they may contain but about two-thirds of the original strength, or two-thirds the amount of antitoxin units. This does not seem to depend entirely upon the preservative used. The ordinary preservatives are camphor, carbolic acid, and tricresol. Variations have occurred with all of these three substances.

The value of the antitoxin unit is estimated entirely upon the reaction of guinea-pigs. These animals though fairly uniform do vary within considerable limits. It is, therefore, possible that in a series of tests the variation in the susceptibility of different batches of guinea-pigs may be great enough to make quite a variation in the standard; that is, for example, one guinea-pig may require one-tenth more than another guinea-pig for a fatal dose. If the stronger guinea-pig be used as a test the antitoxin sample tested would contain one-tenth less number of antitoxin units than the same sample tested on the other guinea-pig, which was weaker and required one-tenth smaller amount of toxin to kill it.

Different manufacturers vary in their ideas of the proper number of units to place in the different grades. Recognizing the fact that serums may gradually lose in strength under various conditions, and believing that a larger number of antitoxin units is absolutely harmless, some manufacturers insert even as many as twice the number of units which they represent to be present upon their labels. Others believe it more accurate to put in only about so many more units as they expect the serum to deteriorate within the time during which they expect it to be used.

Another cause of variation in the strength of the different preparations of antitoxins is that the various preservatives used cause a marked deterioration in the antitoxins. It is necessary, therefore, to always test the antitoxins after the addition of the preservative in order to know the number of units present in a completed and bottled preparation.

It is apparent that the difficulties to be surmounted before serum antitoxin can claim a place among the established reliable therapeutic agents are still very great. But when an exact system of dosage shall have been established, and when serum of a uniform standard strength shall always be at hand, the great obstacles in the way of its complete acceptance will be eliminated.

THE USE OF ANTITOXIC SERUM IN THE TREATMENT OF DIPHTHERIA UNDER THE SUPERVISION OF THE NEW YORK CITY HEALTH DEPARTMENT, WITH A RESUME OF THE PUBLISHED REPORTS ON THIS SUBJECT.

By HERMANN M. BIGGS, M.D.,
OF NEW YORK;
PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES, NEW YORK HEALTH DEPARTMENT,
AND
ARTHUR R. GUERARD, M.D.,
OF NEW YORK;
ASSISTANT BACTERIOLOGIST.

(Continued from page 683.)

WITH a view to a more complete study of the fatal cases of diphtheria occurring in New York during the last few months, a letter has been addressed to every physician who reported a death from diphtheria or croup, asking for information as to whether antitoxin was employed in the case, and if so, on what day of the disease it was administered, and what was the condition of the patient at the time of administration. Personal observations on the subject were also requested.

Information has been received, between May 7 and November 1, 1896, from 306 physicians, with regard to 336 fatal cases of diphtheria reported to the Board of Health—124, or thirty-seven per cent. of these, were reported as treated with antitoxin, and 212, or sixty-three per cent., were reported as treated without antitoxin. The total number of deaths from diphtheria and croup reported during this period was 658. There were, therefore, 322 deaths with regard to which no information was received in response to the letter of inquiry.

Of the 124 fatal cases treated with antitoxin, 41, or thirty-three per cent., were reported as moribund or hopeless at the time of injection, or as dying within twenty-four hours after the first injection, and hence the antitoxin could not have been expected to have any effect; 33 cases, or twenty-six per cent., were injected on the fifth day of the disease, or later, when the remedy has relatively little value; 29 cases, or twenty-three per cent., were complicated with sepsis, scarlet fever, measles, bronchopneumonia—notably bad cases; and 13 cases, or ten and one-half per cent., died from cardiac paralysis, sudden death "resulting from getting up too soon, contrary to instructions."

Of the 212 fatal cases where no antitoxin was used, 50, or twenty-four per cent., were moribund or hopeless when first seen, and hence no antitoxin was used, as stated by the attending physician, because of the patient's condition; 33 cases, or sixteen per cent., were seen too late, in the opinion of the attending physician, for antitoxin to be of any use; 17 cases refused treatment with antitoxin, though strongly advised; and 4 cases were not injected, because being complicated with scarlet fever, measles, etc., antitoxin was considered useless. In 94 cases, or forty-four per cent., antitoxin was not administered, because the attending physician was opposed to its use, was doubtful of its efficacy, or no reason was given. A number of physicians stated that in future they intended to use antitoxin owing to the bad results obtained by other methods. A very large majority of the physicians from whom reports were received (over two-thirds), expressed themselves as strongly in favor of the use of antitoxin in diphtheria. Many of them presented records of previous severe cases treated with antitoxin with good results.

A report is also presented which was prepared by Alfred L. Beebe, Ph.B., Assistant Director of the Diagnosis Bacteriological Laboratory. This includes a series of tables and charts, showing the actual and relative mortality from diphtheria and croup in New York, Berlin, and Paris, previous to and following the introduction of antitoxin in these cities. Mr. Beebe's report follows: "In accordance with your directions the following tables and charts have been prepared from the official statistics of New York, Paris, and Berlin, with a view to show the effect, if any, produced by the use of diphtheria antitoxin on the actual and relative mortality from diphtheria and croup in these cities.

Table 8 gives the annual actual mortality in New York from diphtheria and croup for the years 1880–1895, the case fatality from diphtheria, 1880–1890, and the case fatality from diphtheria and croup combined, 1891–1895, and from January to October, 1896. Croup was not officially classed as a contagious disease by the New York Health Department prior to 1891, and cases of this disease were therefore not required to be reported to the Department. It will be noticed that in the first two years after the reporting of croup is required, the mortality from diphtheria is raised nearly 10 per cent. by the croup deaths (27.9 per cent. to 36.7 per cent., and 30.9 per cent. to 40.6 per cent.). After this the influence of the croup deaths becomes less, as in 1893 the Health Department declared that membranous croup was in the vast majority of cases laryngeal diphtheria, and would be so regarded by the Department. After this announcement the relative proportion of deaths ascribed to croup gradually diminishes, until in 1895 the croup deaths equaled only about one-fifth of the diphtheria deaths, while in 1891, and before, they equaled from two-fifths to one-half or more the number of diphtheria deaths. In no single year until

[1] Antitoxin largely used.

[2] Mortality for first half of 1896.

1895 did the number of cases of croup reported equal the number of deaths. Owing to the rapidly fatal termination of the majority of cases of croup, the report of death was either the first report received by the Department, or the report of the case and of the death arrived almost simultaneously."

Bearing the above in mind, it is evident that the figures for case fatality from diphtheria, 1880–1890, are not comparable with those showing the combined fatality from diphtheria and croup, 1891–1895. The figures for case fatality from diphtheria alone are relatively lower from 1891–1895 than before, as is shown by the table, and as the figures for case fatality from diphtheria and croup combined undoubtedly show the true mortality in diphtheria, they are absolutely, as well as relatively, too low for these years. On the other hand, progressing backward in the scale of years, an increasing percentage of cases of diphtheria were not reported, and the case fatalities for these years are therefore higher than the truth, especially in the earlier years for which figures are given. Taking all the facts into consideration, it seems probable that for the earliest years for which figures are given, the case fatalities for diphtheria alone are somewhat too high; that for the years immediately preceding 1891 they are too low; while for the immediate years they are more nearly correct.

(To be continued.)

REVIEWS.

A TREATISE ON SURGERY. By American Authors. Edited by ROSWELL PARK, M.D., Professor of Surgery and Clinical Surgery, Medical Department, University of Buffalo, Buffalo, N. Y. In two very handsome octavo volumes, comprising about 1600 pages, with about 800 engravings, largely original, and about 40 full-page plates in colors and monochrome. Volume I, General Surgery and Surgical Pathology. Volume II, Special Surgery. Lea Brothers & Co., Philadelphia and New York, 1896.

A critical review of the first volume of this treatise will convince the reader that it will at once assume a position as one of our best surgical text-books. The work, as a whole, will compare favorably with any other, and in many respects this volume is superior to the first volume of other surgical treatises. This is especially true in regard to the chapters written by the editor, who contributes three hundred pages. The other chapters are written by teachers of note and, as a rule, they are clear, comprehensive, and concise. The volume does not contain a chapter which is not thoroughly up to date. The editor has shown his wisdom in stamping each chapter with the author's name.

In the preface he says: "The importance of bacteriology is everywhere recognized, and its teachings are impressed upon almost every page." This is true of the volume as a whole, and especially so of Dr. Park's contributions; indeed, in this respect, his treatise is decidedly in advance of any other surgical text-book. At the same time, the work is eminently practical, and credit must be given to the editor and other contributors for the logical application of scientific facts to routine practice. Such a clear adaptation of pathology to practical work will be of great use to the busy practitioner, and it will enhance the student's interest in a branch of surgery which at times seems to him tedious.

The volume contains several chapters on subjects which we do not expect to find in a surgical work. Their presence adds to the interest and value of the volume. One of these is on the surgical pathology of the blood. Another on autoinfection will be of especial use to the younger class of surgeons, who are apt to entirely overlook the influence of the "constitution" of the patient on the outcome of operation or surgical disease. In the chapter on acute intoxications is found an excellent description of delirium tremens, which disease certainly deserves a place in a surgical work. In another chapter is also an interesting account of immunity and predisposition to infection by the pyogenic bacteria.

The volume is divided into five parts and thirty-seven chapters. Part I treats of surgical pathology, and its five chapters are written by the editor—probably the most valuable part of the volume. Of especial interest is his statement regarding the diagnostic value of leucocytosis. The chapter on inflammation is admirable. The description of chemotaxis and the formation of pus is especially clear. His story of inflammation and suppuration may be, as he says, rather romantic, but it will certainly impress the mind of the student. However, his classification of the causes of gangrene must be regarded in a large degree as arbitrary.

Part II treats of Surgical Diseases. The advice as to preparation of patients for operation is, on the whole, judicious, though it will be apt to influence students to rely too much on drugs, instead of the *vis medicatrix naturæ*. His description of the difference between sapremia and septicemia is clear and good, though his definition of the former term is not elegant. In the treatment of poisoned wounds details are somewhat lacking. He gives a good account of erysipelas, but under treatment fails to mention the methods of limiting the disease by crisscross-incisions or by antiseptic injections around the erysipelatous area.

In the chapter devoted to the consideration of tuberculosis, such terms as *psophylactic*, *archepyon*, *pyoid*, and *puruloid* are noted. These terms, suggested by Dr. Park a year or two since, have failed to obtain the sanction of the profession, probably through no fault of the words themselves. The propriety of applying the term gummata to any but syphilitic masses is very questionable. In his opinion "tuberculin (Koch's) is a remedy of great value when judiciously used in selected cases."

Chapter X, by J. A. Fordyce, on syphilis, is well written, and will be a safe guide for the student and an excellent *resumé* for the busy practitioner. There are several excellent colored plates. The chapter on gonorrhea, by N. T. Belfield, gives a fair presentation of the subject. He says too little, however, about the destructive effects of the disease in the female.

The chapter on shock and collapse is concise, but it seems out of place between sections on gonorrhea and scurvy.

Part III treats of Surgical Principles and Methods and Minor Procedures. The first two chapters are written by J. Parmenter. They are satisfactory. A needed warning against the use of styptics is omitted, and surgeons will hardly agree that the "granny-knot is thoroughly secure."

In the chapter on anesthesia, by H. A. Hare, the indications for the use of the different anesthetics are clearly and judiciously set forth. In the treatment of ether-vomiting, too little stress is laid on the importance of letting the stomach alone and avoiding drugs. The method of inversion described as Dr. Kelly's antedates Dr. Kelly's birth.

Part IV, on Injury and Repair, begins with a chapter on wounds, by C. B. Nancrede, and is followed by one on gunshot-wounds, by the same author, which is most interesting. It is very full and explicit and is illustrated by many excellent cuts.

Part V treats of Surgical Affections of the Tissues and Tissue-systems. The chapter on cysts and tumors, by Dr. Park, is one of the best. Space will not allow of more than mere mention of several excellent chapters in this part, such as those on malformations, ruptures, and tendons, etc., by H. L. Burrett; on injuries and diseases of the lymphatic vessels, by F. H. Gerrish; on the veins, by J. M. Holloway; on the arteries, by Duncan Coe, and skin-diseases, by W. A. Hardaway.

The chapter on injuries and diseases of the joints is an admirable one. The short section on general considerations teems with valuable facts expressed in a clear and concise manner; indeed, this is true of the entire chapter. H. H. Mudd considers fractures and dislocations in two excellent chapters.

An index of twenty-two pages is adequate and not too elaborate. The whole volume is singularly free from errors. The proof-reading has been most careful. In such a large work there must, of course, be a few oversights, as the sentence beginning the paragraph on page 27; but the reviewer, after careful perusal of the work, has been able to discover only one or two others. This volume will certainly meet with success. Both for the student and practitioner it will be a most valuable work. It is thoroughly practical and yet thoroughly scientific. The paper, type, and illustrations are good, and the volume presents a handsome appearance.

A Practical Treatise on Medical Diagnosis. For the Use of Students and Practitioners. By John H. Musser, M.D., Assistant Professor of Clinical Medicine, University of Pennsylvania, Philadelphia. New (2d) edition; thoroughly revised. In one octavo volume of 925 pages, with 177 engravings and 11 full-page colored plates. Cloth, $5.00; leather, $6,00. Lea Brothers & Co., Publishers, Philadelphia and New York. 1896.

The exhaustion of the first edition of a work of this character and scope within eighteen months of its publication is unusual and complimentary alike to the author and to the medical profession.

In the preparation of this volume the writer has set up for himself the very highest ideals. It would be well if all students and many practitioners of medicine would learn this sentence from the preface: "Partial knowledge of the nature of a case differs merely in degree from ignorance, and treatment based on either invites chances unjust alike to the patient and to the interest of the physician." It is in the spirit of this declaration that every chapter has been written, and it is with the same question as to thoroughness and completeness that the author has taken advantage of the exhaustion of the first edition to revise the entire work. By so doing, every real advance that has been made in this rapidly progressing department of medicine is here recorded, and made available in a single volume. This is especially noticeable when one compares the two editions, topic by topic, or even page by page. There is no half knowledge. There is no looseness in the use of words. The author's style is clear and pointed, and yet smooth. His descriptions of the diagnostic manifestations of diseases are accurate, and not overburdened with words. The methods of conducting the physical examinations of the various organs of the body are admirably inculcated, and the results to be looked for are described in terms that are precise and yet easily comprehensible. The points of differentiation in diseases, presenting more or less similarity, are clean cut.

There is such fulness and so much detail in the author's chapters on the chemic, microscopic, and bacteriologic examinations of the pathologic products in diseased conditions, that the book can be used as a working laboratory text-book on these subjects.

The arrangement of subjects is convenient. The first six chapters, covering 191 pages, are devoted to general diagnosis, and comprise the following subjects: General Observations, The Data Obtained by Inquiry, The Data Obtained by Observation, Bacteriological Diagnosis, The Examination of Exudations, Transudations and Cystic Fluids, and The Morbid Processes and Their Symptomatology. The remainder of the book, a total of 718 pages, is given to Special Diagnosis, in which the organs are taken up seriatim, and the manifestations of each disease are thoroughly discussed. There are comparatively few cross-references, and a competent index makes easy work of looking up any subject in its entirety. This is a great advantage to the student, for this grouping together, by his own efforts, of the symptoms of a given disease, the descriptions of which are to be found under different heads, is sometimes difficult and always annoying.

The illustrations are sufficiently numerous, perhaps, although they might have been used to advantage in some instances where not employed. The engravings illustrate, however, and do not serve simply to embellish. The number of colored plates in this edition is increased from two to eleven, and they are admirable samples of artistic work.

It is certain that the revised edition of this work will meet all the requirements of student and physician, and that it will long hold its place as one of the most notable contributions to scientific medicine.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

ORIGINAL ARTICLES.

NOTES ON THE REACTIONS AND TESTS OF BILE PIGMENTS IN URINE AND OTHER ORGANIC FLUIDS.

BY J. B. NICHOLS, M.D.,
OF WASHINGTON;
CLINICAL ASSISTANT, UNITED STATES SOLDIERS' HOME, WASHINGTON, D. C.

THE primary pigment-substance of the bile is bilirubin. From it are derived a number of secondary pigments that occur in various fluids of the body, while still others may be produced experimentally. Under the action of certain reagents, probably setting up a process of oxidation, a series of differently colored pigments is formed from bilirubin. Bilirubin, with its characteristic rich amber or brown color, is first transformed into the green biliverdin; this in turn changes into a blue pigment (bilicyanin), followed by a purple red and then, it is said, a yellow substance. Of these pigments, bilirubin and biliverdin are of common occurrence in organic fluids.

The numerous tests recommended for the detection of bile-pigments mostly depend upon this reaction. There are other pigments or pigment-forming substances in the organism that afford red, purple, and other color-reactions with mineral acids; but the distinguishing characteristic of bilirubin is its primary transformation into a green pigment (biliverdin). The essential feature of the ordinary tests for bilirubin is the appearance of an initial green—which may, however, be very transient—under the action of certain reagents. The various processes differ as to the reagents employed (mineral acids and halogen bodies) and the manner of applying them.

The results of a number of observations which I have made as to the effects and relative sensitiveness of various reagents and tests applied to aqueous dilutions of bile, removed after death from the human gall-bladder, appear to be worthy of note. The stronger dilutions of bile (down to about 2 or 3 of bile to 100 of water) are deep brown, and on agitation produce a profuse golden froth. As the dilution becomes more attenuated the brown gradually passes into a rich golden or bright amber. Dilutions of 1–1000 present a well-marked amber color, while in dilutions of 1–10,000 a yellow tinge is still plainly perceptible on looking through a depth of 20 or 30 centimeters of the fluid.

The color-reactions produced by various reagents upon diluted bile are as follows: Pure sulphuric, hydrochloric, or nitric acid, mixed in small proportion with dilutions (five-tenths to two per cent.) of bile, cause a slow change of its color from yellow to green. Several hours may elapse before the change is effected. If the acid be added in larger proportion, the color changes more rapidly, while in very large proportion the green may further change to blue and purple tints. Pure nitric acid is more powerful in effecting the color changes than either sulphuric or hydrochloric acid.

The impure yellow nitric acid of commerce, containing lower oxids of nitrogen, is far more energetic in its action on bilirubin than are the pure mineral acids, and is a very satisfactory reagent for testing purposes. Three or four drops added to about five cubic centimeters of a five-tenths to two-per-cent. dilution of bile, produces a bright green color, immediately or after a short interval; a larger quantity (8 to 15 drops) causes an immediate change to bright grass-green, which soon turns blue, and then purple red. If the fluid be heated, the vigor and rapidity of the reaction are much increased. A mixture of equal parts of pure nitric and hydrochloric acids, prepared immediately before using (the mixture soon turns yellow), was found to produce the color changes in the same manner as does commercial nitric acid, and with equal, or perhaps even greater, energy. Hydrogen peroxid—the commercial article, which contains a small amount of acid—causes a gradual change of color to green.

Very striking reactions were obtained by mixing about five volumes of diluted bile with one volume each of hydrogen peroxid and a strong solution of sodium bromid, and then rapidly mixing with this one-half to one volume of either nitric, hydrochloric, or sulphuric acid. The yellow color of the fluid immediately changes to a green, quickly turning blue and then purple-pink, then more slowly changing to gray, and lastly to yellow. The final yellow does not appear to be due to the bile, but is produced by reactions among the reagents added (perhaps the liberation of bromin). The initial green may pass into the blue so rapidly as to be overlooked if not carefully observed. The changes of color in rapid succession, and their strong contrasts, as in the similar effects producible by commercial nitric or by nitrohydrochloric acid, afford a very striking

reaction. The addition of grape-sugar was not found to affect the reactions in any way.

There are various modes of applying the reagents so as to obtain these color-reactions, as (1) by mixing the fluids intimately, as above indicated; (2) by underlaying the bilirubin-containing fluid with the acid, or (3) by allowing a few drops of each of the fluids to flow together on a white plate.

The color-reactions that occurred on intimately mixing the reagents employed—commercial nitric acid, the nitrohydrochloric acid-mixture, and the mixture of sodium bromid, hydrogen peroxid, and acid—with the fluid were perfectly characteristic and well marked with bile diluted with water as far as the proportion of about 1–200 or 400 (varying with different specimens of bile); below that strength, the reaction became less conspicuous.

The contact method, carried out by underlaying the diluted bile with the acid employed (as in the contact test for albumin), is of equal availability and sensitiveness. At the junction of the two fluids there is usually a colorless layer; above this are layers of reddish purple, blue, and green, from below upward; the green diffuses through the upper fluid, and after a time is replaced by the blue. Below, the acid is pale yellow. In case the sodium bromid and hydrogen peroxid are employed, they may be mixed with the fluid, and the whole then underlaid with the acid. The green layer was distinctly marked in dilutions as low as about 1–200 or 400; below that strength some play of colors was present, but the green color, which is the essential element in testing for bilirubin, became indistinct.

A test very commonly recommended for bile-pigments consists in placing a few drops each of impure nitric acid and the fluid to be tested on a white porcelain dish, and causing them to flow gently together. A play of colors, beginning with green, at the junction of the fluids, indicates the presence of bilirubin. Tests of this method showed it to be sensitive with dilutions of bile to about 1 in 50 or 100; in weaker dilutions a marked play of colors occurs, but no distinct green is present. The methods of mixture or underlaying with the reagent, which are equally easy of application, plainly exhibited the reaction in fluids containing at least one-fourth as much bilirubin, and are therefore about four times as delicate. Moreover, icteric urines occur which give marked response to the mixture or contact-tests, but none distinctly with the plate method. It would seem, therefore, that the white-plate test for bilirubin should be discarded. A number of other methods of carrying out the test, which have been recommended, were briefly tried, but none was found more sensitive or simple than those mentioned above.

Occasions for testing for the presence of bilirubin arise chiefly in connection with the urine. The appearance of urine containing bilirubin is usually almost characteristic. The color is a rich, clear, brownish or bright amber; on its surface a golden froth forms freely on agitation; in consistency, the fluid is perhaps a trifle thicker than usual, and it may impart a yellow color to sediments and precipitates, or to paper moistened with it. Either yellow commercial nitric acid, or a fresh mixture of equal parts of nitric and hydrochloric acids, may be conveniently used to test for bilirubin. If the urine be very dark it may be advisable to dilute it. Three to fifteen drops of the acid may be mixed with five to ten cubic centimeters of the urine to be tested; or the urine may be underlaid with the acid. The presence of unmodified bilirubin is indicated in the former case by the liquid turning a bright or a dark green, either immediately or after a few minutes, perhaps followed subsequently by blue and red colors; in the latter case by the appearance of a green color or layer, above the other colors.

If commercial nitric acid be used in carrying out the common heat-and-nitric-acid test for albumin, the same procedure may serve for both tests, as the hot urine will readily turn green on adding sufficient acid if bile-pigments are present, or the albumin may be precipitated green.

A good arrangement of light for observing the contact-test is to hold the test-tube before white paper, placed at such an angle that the light from the window falls directly upon it, and is thence reflected to the eye of the observer through the fluid.

Other pigments in urine that produce striking red, blue, and other color-reactions with acids, but no green, must be carefully distinguished from bilirubin. Conversely, in order not to interfere with other tests, as for indican, bile-pigments may be precipitated by the addition of lead-acetate solution.

When bile is vomited from the stomach the color of the fluid is frequently or usually green, due to the presence of biliverdin derived from bilirubin by the action of the hydrochloric acid of the gastric juice. On adding the usual acid reagents, the green color becomes blue, the process of oxidation being thus carried a step further.

It occasionally happens that the urine from icteric patients, although presenting the color and other appearances of containing normal bile-pigment, does not respond to the tests of bilirubin. Instead of green, a red or even a blackish color may appear. In these cases the bilirubin has undergone some transformation, perhaps reduction to urobilin, and is incapable of being converted into biliverdin.

THE PRACTICAL VALUE OF THE RÖNTGEN-RAY IN THE ROUTINE WORK OF SURGICAL OFFICE PRACTICE.

BY MAURICE H. RICHARDSON, M.D.,
OF BOSTON, MASS.;
VISITING SURGEON TO THE MASSACHUSETTS GENERAL HOSPITAL;
ASSISTANT PROFESSOR OF CLINICAL SURGERY,
HARVARD UNIVERSITY.

(Continued from page 688.)

An important consideration in connection with skiagraphy in any form is the occasional burning of the patient. At first it seemed impossible that the Röntgen-ray could cause any injury to the skin. The explanation seemed to lie rather in a direct contact with the electrical currents, thrown off either from the tube or from the wires—currents too small, perhaps, to be visible, or to cause any distinct sensation of pain. This theory seems untenable, however, in view of the fact that in some cases of undoubted burning, the Crookes tube has not been held nearer to the skin than eighteen inches. I have used the machinery now some three or four months almost daily, and have had no ill effects in any of my cases. In this community, however, two undoubted cases of injury, following the use of the X-ray, have been observed. One is referred to by Dr. J. C. White in the *Boston Medical and Surgical Journal* of December 3, 1896, page 583. In Dr. White's letter is mentioned a case of "Dermatitis caused by X-rays," published in the *British Medical Journal* of November 7th. Dr. White mentions also a case under the care of Dr Warren at the Massachusetts General Hospital: "A young lady was exposed to the rays for half an hour on one day, and forty-five minutes on the following day, the tube being placed about six inches in front of her sternum. On the following day the skin over this region became red, and later 'blistered.' Three months subsequently, when seen by me at the request of Dr. Warren, early in October, there was an area of angry-looking granulations some three inches square, which had obstinately refused to 'heal.' The surface was very sensitive, and the region was the seat of severe neuralgic pain. It is reported that at the present date, November 15th, two small 'open' spots persist, and that the region is still painful."

I saw this case of Dr. Warren's when it first entered the hospital; some doubt was then expressed as to the source of the irritation. It was thought that minute sparks from the tube might have affected the skin. A much more distressing case has lately been called to my attention, through the courtesy of Dr. Stickney of Beverly.

Dr. Stickney writes:

"The patient, Mrs. Q., came under my care last August, at which time she was suffering from some obscure abdominal trouble. She wished to have the X-ray used on her as a possible means of diagnosis, and with that purpose in view made her arrangements with an expert in skiagraphy, and requested me to be present. The whole abdominal region was exposed to the X-ray, but the force of the ray was focused more to the region of the liver, as that was where she complained of her trouble. There were three exposures made—one of twenty minutes, one of thirty minutes, and the last of thirty-five minutes. The Crookes tube was not brought nearer than eighteen inches to the parts exposed.

"She experienced no discomfort at the time, but some two days after called at my office, complaining that the region exposed to the X-ray felt as though it had been burned by the sun. Upon examination I found the appearance of the parts exposed to be similar to that seen in severe forms of sun-burn. The condition of the parts from this time grew rapidly worse, until a surface some eight inches in diameter had sloughed. The slough was very slow in separating, and the surface has been very slow in filling in, the vitality of the parts seeming to have been affected much deeper than the slough would indicate. All the different treatments for burn and ordinary lesions of like nature have been adopted, together with a thorough curetting, but nothing seems to be of much assistance. The lesion has been very painful from the first.

"At the present time the surface has cicatrized, so that a surface of four inches in diameter is still left unhealed."

It would seem, from the experience derived from these two cases, that the trouble comes from long and continuous exposure.

It is essential, therefore, before subjecting a patient to prolonged examination by the X-ray, to warn him that in rare instances the skin is affected.

CASE X.—A. F., aged nineteen, a football-player, was injured in his left shoulder. There was great tenderness in the outer extremity of the left clavicle. It was impossible, six hours after the injury, to make out crepitus or deformity. A skiagram, taken after an exposure of some six or eight minutes, showed a solution of continuity at the seat of pain. On the strength of the fluoroscopic examination, the arm was put up in a Velpeau bandage. The young man evidently regarded the injury as trivial, for he never appeared again. I was informed, however, by the surgeon of the football-squad, Dr. Balch, that a callus appeared at the point of tenderness a week or more after the injury.

CASE XI.—October 26, 1896: Mr. G., aged fifty-one, four weeks ago began to have pain in the upper jaw. A tumor was conspicuous, through which the X-ray passed without interruption, except from a loose fragment, evidently a sequestrum. Operation

showed an extensive necrosis of the upper jaw, with a loose piece of dead bone, as shown in the skiagram.

CASE XII.—October 27, 1896. Mr. C., aged fifty-two, a syphilitic with extensive ulcerations over the tibia. By digital examination there seemed to be an increase of bony substance. A skiagram, taken after an exposure of six minutes, showed the tibia perfectly smooth, without loss of contour or increase of bony growth.

CASE XIII.—October 27, 1896. Miss B., a nurse, aged thirty-two, after a septic wound of the middle finger of the right hand, had not been able to straighten the finger for some weeks. The skiagram showed a bony ankylosis.

The distal end of the first metatarsal bone was removed and the great toe brought into the normal line. The man made a rapid recovery. A skiagram, taken a month or two after the operation, showed in an interesting manner the position of the cut surface of the metatarsal bone, with reference to the first phalanx.

CASE XVII.—Doctor ——, aged forty-four, in playing polo had received an injury to the first interphalangeal joint of the middle finger. There was considerable thickening, apparently of bone; yet both fluoroscope and skiagram showed that the bony portions were perfectly healthy. Evidently the case was one of traumatic arthritis without injury to the bone.

FIG. 4.

CASE XX.—Fracture of the Clavicle.

CASE XIV.—October 27, 1896. Judge ——, aged fifty, had received an injury to the left wrist, and feared that the bones had been injured. The fluoroscope showed nothing abnormal. After an exposure of four minutes to a Carbutt plate, a very beautiful demonstration of the bones was obtained, which showed them to be perfectly intact.

CASE XV.—I. F. C., aged forty-two, had an extensive swelling of the right knee, which was shown by the fluoroscope and by the skiagram to involve extensively both tibia and femur. The outline of the diseased parts could be clearly seen.

CASE XVI.—Mr. B., aged fifty-nine, had had for ten years a marked hallux valgus. Examination with the fluoroscope showed the exact position of the bones.

CASE XVIII.—A man of about fifty-seven years received in a planing-machine a severe injury to the right elbow, which required the removal of a portion of the ulna near the elbow. There was marked impairment of function. Examination with the fluoroscope showed no abnormal position of the bones. The skiagram confirmed this. The ankylosis was evidently functional rather than organic, and the man has been put upon massage and passive motion.

CASE XIX.—Mr. D., aged thirty-eight, had a Pott's fracture of the ankle, received from a fall in the street. There was marked eversion of the foot —much more than the position of the fragments would seem to explain. The skiagram shows a fracture of the fibula, with some injury to the internal

malleolus, and a forward displacement of the tibia. No bony injury to the tibia could be made out. The patient was sent to Dr. Goldthwait who applied a steel support.

CASE XX.—A man of thirty-two, in September, 1896, fell from his bicycle and received an injury to the left shoulder. He was treated in a hospital. I first saw him two months after the injury. Nothing abnormal could be detected on inspection. Careful digital examination revealed a slight deformity of the left clavicle. There had evidently been some kind of fracture, but the result was extremely good. The skiagram (Fig. 4) shows excessive displacement of the fragments. Such a skiagram as this would certainly indicate to the lay mind a deplorable lack of skill. The surgeon knows, of course, that such results cannot be prevented, especially in the clavicle.

CASE XXI.—Mr. X., aged thirty-four, shot himself through the thorax with a thirty-two caliber revolver, in November, 1893. The wound of entrance was two inches above and to the right of the left nipple. It was hard to see why the bullet had not penetrated the heart. Complete and lasting recovery followed. In September, 1896, in examining with the fluoroscope, I could see the bullet distinctly in the left and posterior part of the thorax under the ninth rib. After an exposure of thirty minutes a faint skiagram of the ribs, scapula and bullet was produced. No operation was performed, as the missile was causing no trouble.

CASE XXII.—Mrs. B., aged sixty-six, has had for years severe rheumatic arthritis in the fingers of the right hand. An exposure of forty seconds gives an excellent idea of the osseous deposit.

Besides the foregoing cases, I have used the fluoroscope in many others—cases in which negative results were of great service to me in forming an opinion, such as demonstrations of the absence of fractures and dislocations, bony ankyloses and tumors. The usefulness of the apparatus is quite as conspicuous in cases of this kind as in those in which a foreign body or a bony deformity is present.

The medico-legal aspects of this subject, though at present uncertain, add strong arguments in favor of routine office skiagraphy. In fractures it is of the greatest importance for the physician's own protection that he should ascertain by the use of the fluoroscope the exact situation of the fragments, even if he has already an accurate idea of their position and shape, for if he does not recognize, even if he cannot correct, a faulty approximation, the deformity is pretty sure, sooner or later, to be detected by a complaining patient. It is only a question of time, I think, when every person who has had a fracture will try to have it photographed by the X-ray. It will then appear, as we all know, that in many instances the bones are not in perfect approximation. Indeed, fragments which have been brought together with the greatest care by the most skilled operators will often show, under X-ray photography, a reduction which, to the patient, appears unskillful. I recall one case in which one of the most eminent surgeons in this country reduced a fracture of both bones of the forearm. Though the position was absolutely perfect, as far as could be judged by any of the ordinary methods of investigation, an X-ray photograph showed that the fragments of the ulna were considerably displaced (see Case 1). The ultimate practical result was most excellent. The imperfect approximation would never have been suspected by ordinary methods of examination. Indeed, it is doubtful whether the fragments could have been better adjusted by the aid of the fluoroscope. Nevertheless, it seems to me, the use of the X-ray is demanded in all cases, for some fractures are sure to be followed by an impairment of function. Unless, therefore, the surgeon can show that he has used every means at his command to understand and treat the fracture (and these remarks apply also to dislocations), his defense in case of legal complications—always liable to arise—must, of necessity, be weakened.

The present aspect of the subject before the courts seems of interest in connection with a physician's responsibility in the case of fractures. I have been recently informed by an experienced trial judge of this Commonwealth that "It is the opinion of some of the judges of Massachusetts that X-ray photographs are not admissible as evidence. One judge holds that it has not been demonstrated as a scientific fact that they are accurate. The process has not become such a matter of common knowledge that the courts will take judicial notice of it. No man can tell by ocular or other sensory evidence that the reproduction is accurate. The truthfulness of the photograph is a matter of reasoning." Other judges do not take this view; they say that there is no reason why an X-ray photograph cannot be substantiated by reasoning from well-known anatomical facts—reasoning which excludes the mistakes and distortions of ordinary photography; that the courts have always received evidence which, by its very nature, must render valuable assistance in investigations; that, moreover, this evidence has not always been confined to that dependent upon the ordinary senses—a form analogous to the ordinary expert evidence; and, furthermore, that the rule of law has allowed not only evidence derived from the use of the five senses, but has also permitted the introduction of evidence derived from the reasoning power, as in the ordinary expert evidence, and the evidence as to customs, and the like. The crucial test will come when an actual case presents itself to the courts with all the side lights of fact and circumstance.

CLINICAL MEMORANDUM.

A CASE OF TUBAL PREGNANCY SIMULATING APPENDICITIS.

BY WM. T. LUSK, M.D.,
OF NEW YORK.

ON the 4th of November last, I was invited by a physician of this city to see with him a young woman, twenty-two years of age, who presented many of the symptoms of appendicitis. Her general health had in the main been good, but six months previously she had been suddenly seized with intense pain of sharp, lancinating character, in the right inguinal region. It persisted for three or four days, during which time the bowels were costive and vomiting was frequent. It then passed away, and except for occasional shooting pains in the right groin, the patient remained well until five days before my visit, when she had a second attack, likewise attended by vomiting and constipation. The pain, which had at first been general, was localized, and the tenderness upon pressure was apparently greatest at McBurney's point. The temperature was 100⅘° F., pulse 96, respiration 20, and there was retention of urine. The evidences of appendicitis seemed to be complete. I was, however, asked to make a vaginal examination. On the right of

the uterus I found a swelling the size of a large orange, which contained fluid, and was firmly fixed in the pelvic cavity. I suggested, therefore, that the patient should be removed to Bellevue Hospital for further consultation, and for operation, should the latter be decided to be necessary.

On her arrival at the hospital on November 5th, the temperature was 100.8° F., pulse 112, respiration 28. The case excited a great deal of interest on the part of the house staff, and of the consultants invited to the examination. It was thought that the skilled finger could detect the thickened appendix. As, however, the theory of appendicitis did not satisfactorily account for the pelvic tumor, I decided upon an exploratory incision in the median line. When the examining finger was introduced through the abdominal opening, it was easy to determine that the appendix was normal, and that no adhesion nor inflammatory condition existed in the vicinity of the cecum. The apparent enlargement of the appendix had disappeared. Below the pelvic brim, a sac with thin, tense walls was felt to the right of the uterus. It completely filled the right pelvic space. Fearing that the sac-contents might prove to be purulent in character, and feeling certain that manipulation would insure its rupture, I aspirated a portion of the fluid from below through the vagina. It proved to be clear and slightly tinged with blood. The removal of about an ounce was followed by the shrinking of the sac, and by the perceptible thickening of the sac-walls. It was then detached and ligated off without special difficulty. It proved to be a tubal pregnancy. The ovum had grown downward between the folds of the broad ligament. The embryo had probably perished in the early weeks, though there remained sufficient decidual and chorionic tissue to establish the character of the sac.

The patient made a rapid recovery, and returned home at the end of three weeks.

The case is interesting because of the question it raises as to whether a positive diagnosis of appendicitis can be made in all cases. Of course, there is no other department of abdominal surgery in which complete immunity against diagnostic error has been affirmed.

MEDICAL PROGRESS.

An Unusual Case of Lockjaw.—SACHSE reported in the *Centralbl. f. Chir.*, No. 40, 1896, an unusual case of lockjaw occurring without known cause in a male, aged twenty-four years. On waking one morning he found he could not open his mouth as far as usual. The disability increased daily, until he was unable to separate the teeth. For four years he was treated without benefit, until it was discovered that the right upper wisdom-tooth pointed directly outward, and so pressed against the internal pterygoid muscle as to prevent the jaw from opening. It was removed with difficulty. Immediately after its extraction the jaw could be partially opened, and in eight weeks function was fully restored.

Thirteen Operations for Recurrent Sarcoma.—In the *Lancet*, November 7, 1896, ELIOT gives the history of a series of thirteen operations performed by him upon a patient, seventy-five years of age, for myxo-sarcoma of the right scapula. The first operation was performed in September, 1892, the patient then being seventy-one years old. The growth recurred in a year, and was again and again removed, at intervals of from one to six months. In May, 1895, the arm was removed, together with the outer third of the clavicle, and what remained of the scapula. The patient made a good recovery, and four months later there was no evidence of recurrence. Eliot is convinced that although the disease recurred and caused the patient's death the removal of the whole extremity was nevertheless advisable, as the extension of the growth into the axilla was causing the patient great pain.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, DECEMBER 26, 1896.

IMMUNITY FROM TYPHOID FEVER OBTAINED BY INOCULATIONS.

PEIFFER and KOLLE have been conducting at Koch's Institute in Berlin a series of experiments with cultures of typhoid bacilli, and have obtained valuable results, some of which are outlined in an article in the *Deutsche med. Woch.*, November 12, 1896. Those who have kept in touch with the discoveries made in connection with the subject of immunity, know that protective inoculation against cholera has been conducted in India on a tremendous scale. In 1895, over 100,000 persons were inoculated, first with a small dose of a sterilized culture of cholera germs, then five days later with the same dose of a living culture, and five days after that with a final larger dose of the living culture. The results were definite, and not entirely unexpected. The inoculated individuals, when compared with others in similar circumstances who were not inoculated, were found to possess to a considerable degree an immunity from cholera.

Experimental research has yielded similar testimony. Thus it is found that 0.5 c.cm. of *normal* human serum is sufficient to save a guinea-pig from death if it is injected simultaneously with a loop full of cholera cultures into the animal's abdomen; a single milligram—indeed in some cases only a fraction of a milligram—of the serum of a *cholera-inoculated* man will avert death if injected in the same way. This specific result with such a minute dose can only be obtained by using the serum of either a person who has recovered from cholera, or, as already said, of one who has been inoculated with cholera cultures.

These results were so definite that Peiffer and Kolle resolved to test the typhoid bacillus in the same way, using for the purpose a most virulent culture obtained from the spleen. A small quantity of this was diluted with bouillon, sterilized, and injected under the skin of a man who had never had typhoid fever. The injection was followed by a chill, dizziness, and a temperature of 38.5° C.—101.3° F. These symptoms disappeared entirely in one day. The serum from the man so treated was drawn before inoculation, and six and eleven days after the inoculation, and used for experiments upon guinea-pigs. The results were found to be analogous to those obtained with cholera germs. At six days the serum showed its power of saving a guinea-pig, if injected into the abdomen with an otherwise fatal dose of typhoid culture. By the eleventh day this immunizing power was still stronger, being then at least as strong as that of the serum of a convalescent typhoid patient.

In the light of our present knowledge it seems that the freedom from second attacks, enjoyed by patients who have recovered from typhoid and certain other fevers, is due to the appearance in the blood of some specific germicidal substances. Their presence insures for a certain time—for months or years it may be—immunity from that particular disease which has produced them. If these artificial inoculations produce in the individual a serum of germicidal power equal to that of a convalescent patient, why will they not confer immunity against typhoid fever just as well as a previous attack of the disease? These investigators believe that this is so, and look for a practical application of the theory in some rapidly spreading epidemic.

It will be noticed that this is quite a different thing from the inoculation of a man already sick. The system in the latter case is already poisoned and reacts very differently to the injection of the serum. As in cholera so with typhoid; this antitoxic serum pos-

sesses a germicidal power, but does not seem to have any counteracting influence upon the toxic products of the typhoid bacilli. In this sense it is not an antitoxin.

THE TREATMENT OF TUBERCULOUS DISEASE OF THE KNEE-JOINT IN CHILDREN.

A most important contribution to the knowledge of the pathology of tuberculous disease of the knee-joint and of the final results of its treatment is presented in the recent report of the cases treated under the direction of Professor Koenig in the hospital at Göttingen during the eighteen years from 1875 to 1893, entitled "Die specielle Tuberculose der Knochen und Gelenke." Koenig calls attention to the fact that there has recently been a general abandonment of the operative in favor of orthopedic treatment, and states that, in his opinion, the reaction has been too great; for while it is true that an ideal result, the cure of disease and the preservation of function, can only be attained by conservative treatment, yet this is possible in but a small percentage of the cases, and that the radical removal of disease offers the only approximately sure method of cure, and is, on the whole, the safest treatment. Although Koenig does not admit the marked distinction, either in the pathology or behavior of tuberculous disease of the adult and the child, that has been claimed by others, yet for economic reasons, and because operative treatment does not offer the same assurance of permanent cure, conservative methods should receive in childhood a thorough trial before radical measures are resorted to. In answer to a possible criticism that more favorable results might have been presented by one who had operated less often, he asserts that no radical operation had been performed until he was assured that recovery with retention of joint function was impossible.

Of the 720 patients admitted to the hospital for the treatment of tuberculous disease of the knee-joint, 323 were children. Of these, 218 were either primarily or secondarily treated by radical operation: by arthrectomy, 128; by resection, 82; by amputation, 8. Simple conservative treatment was attempted in 128 cases, 83 children and 45 adults. In 117 of these, the final results are known; in 52 the treatment had been abandoned; in 49 (40 children and 9 adults) the results are classed as good, although of these but 14 recovered with a movable joint, and of the remainder the leg was deformed in one-half. Other cases (53 children) were treated by injections of iodoform-glycerin, by atypical operations, and the like, but it is impossible to separate the results from the larger number of adults similarly treated.

This proportion of operations on children shows either an advanced stage of disease or deformity, or else a tendency on the part of the surgeon toward radical treatment, while the results in the non-operative cases are bad enough to warrant the conclusions that have been drawn from them. On the other hand, the report shows that effective orthopedic treatment was lacking, except during the period of hospital residence; Koenig does not use apparatus because it is ineffective, and because of its expense; consequently all the protection that the joint received during the greater part of the treatment was that afforded by plaster-bandages applied at infrequent intervals.

It may be of interest in this connection to compare these statistics with those reported by Gibney (Transactions of the New York Academy of Medicine, vol. ix, 1893), showing the final results in 300 cases of tuberculous disease of the knee in children, treated during a similar period of twenty years at the Hospital for Ruptured and Crippled and elsewhere, by what may be termed, by comparison, ultraconservative methods. Radical operations were performed in but 16 instances, as contrasted with 218 in Koenig's list. In sixty-three per cent. of all those on whom conservative treatment was begun, it was continued to the end, and the patients were cured, as contrasted with fifty per cent. of Koenig's selected cases. Of 242 living patients, including those still under treatment, seventy-nine per cent. retained motion in some degree, thirty-eight per cent. of these from a range of 45° to normal. In a smaller group, treated by modern protective methods, motion was retained in ninety-five per cent. Although suppuration had at some time been present in nearly half of the cases, the death-rate from all causes was but 13.3 per cent.

In this country the orthopedic treatment of chronic joint-disease long antedated the knowledge of its cause, and this treatment, supported by the study of its effect upon the symptoms of the disease, and of

the functional results attained by it, has been modified rather than displaced by the better understanding of its exact pathology. Consequently, the patients have been spared in great degree the unnecessary and mutilating operations that were at one time in favor elsewhere.

The ideal result, as it is styled by Koenig, the cure of local disease and the preservation of function, at least in part, is not in childhood considered a remote possibility, but as a result that may be attained in a large proportion of cases treated under proper conditions. It is a result made probable by long-continued and effective protection of the diseased joint. Such protection must include the removal of superincumbent weight, and the cessation of joint function by fixation as complete as possible. Deformity, if present, must be rectified, and must never be allowed to recur. To this fundamental and essential protection all other surgical treatment is secondary, and it is believed that only when combined with such protection can the relative value of antituberculous injection or the method of passive congestion, or the minor operative procedures be ascertained, or the necessity or advisability of radical operations be properly estimated. For, while pathology, as Koenig insists, must be the basis of treatment, yet the condition of a joint revealed at operation depends in great degree upon the quality of the patient and upon the treatment that has preceded the operation. It may be true that there is no essential difference in the disease of the adult and the child, yet early excision is often the treatment of choice and necessity in the former, because practical experience has proved, aside from the economic question involved, that conservative treatment is more difficult, that the course of the disease is longer and more depressing, and that the outcome, both as regards mortality and functional results, is much less favorable than in childhood.

It is very evident that Koenig's conclusions cannot be accepted as applying to the treatment of knee-joint disease in this country. The great value of his work will be rather in the opportunity that it affords for the study of the intimate nature of the local tuberculous process, from its inception to its end.

Finally, we may conclude that the best statistics will be furnished by those patients on whom effective protective treatment has been early applied, and persistently and faithfully continued. This treatment must, from the nature and duration of the disease, be in a great degree ambulatory, and therefore orthopedic in character, and it is only in conjunction with such treatment that the advances toward the more rapid cure of disease, whether by operation or by any form of local medication, will be made.

Royal Whitman, M.D.

ECHOES AND NEWS.

Death of a Kansas Physician.—Dr. Selden W. Jones, one of the oldest practising physicians in Kansas, died at Leavenworth last week.

Resignation of Dr. Lloyd.—Dr. Samuel Lloyd has severed his connection with the editorial staff of the *American Medico-Surgical Bulletin.*

Changes in Parke, Davis & Co.—Mr. George S. Davis has withdrawn from the corporation of Parke, Davis & Co., the well-known manufacturing chemists, whose headquarters are at Detroit, Mich.

An American Physician Dead in Chili.—Dr. James H. Trumbell, formerly of New Haven, Conn., died recently at Iquique, Chili. He was graduated from Yale College with the class of 1848, and from the College of Physicians and Surgeons, New York, in 1852. He had resided at Talcahuano and Concepcion, Chili, for more than forty years.

Assault upon the Author of "Ben Bolt."—Dr. Thomas Dunn English, one of the oldest living graduates of the medical department of the University of Pennsylvania, and the famous author of "Ben Bolt," was assaulted by a tramp at his home in Newark, N. J., recently, but escaped without serious injury. His assailant was taken into custody after a lively chase, and was held for trial.

Bees to make Medicated Honey.—According to a Paris journal a Frenchman has been trying to compel bees to make medicated honey. He keeps the bees under glass and gives them only flowers that have the desired properties. Thus he obtains different kinds of honey by which influenza, coughs and colds, indigestion, asthma, and many other ills are said to be readily if indirectly reached.

An Interesting Lecture at Bellevue.—Dr. T. M. Rotch of Boston, lectured by invitation before the students of Bellevue Hospital Medical College on December 15th, last, on the Differential Diagnosis in the Eruptive Diseases of Children, with special reference to scarlet fever and its complications. The lecture was illustrated with colored lantern slides, and was exceedingly instructive and interesting.

"The Devil's Club."—There recently arrived in Portland, Ore., a miner from Alaska in search of surgical aid. His face and hands were filled with the poisonous barbs of a plant known as the creeping devil's club, *Panax horridus.*

The unfortunate man presented an appearance resembling the most aggravated erysipelas, and gave evidence of constitutional infection. Free incisions were often necessary to extract the thorns which incline to sink deeper and deeper into the tissues. Contact with this vine is one of the accidents of Alaskan travel most dreaded by prospectors.

Aiken Cottage Sanitarium.—Dr. C. F. McGahan has recently opened a Cottage Sanitarium at Aiken, S. C., for men only, who are suffering from the first stage of pulmonary phthisis. The work is modeled on philanthropic lines, a nominal weekly charge being made in order to exclude the pauper class, who are provided for elsewhere. The only similar institutions of this kind in this country are those conducted by Dr. Trudeau, at Saranac Lake, in the Adirondacks, Dr. Bowdich, at Sharon, Mass., and the Loomis Sanitarium, Sullivan County, N. Y.

Malignant Anthrax at Sing Sing Prison.—A convict in Sing Sing prison has recently developed a case of malignant anthrax, the result of scratching a pimple on his neck with his finger nails. He had been handling curled hair, such as is used in upholstery work, and it is supposed that the anthrax spores had collected under the nails. He has had violent hemorrhages from the nose and mouth, and his left side is completely paralyzed, but Dr. R. T. Irvine, the prison physician, thinks his chances of recovery are good. It is said that only about a dozen cases of this disease in man have heretofore been reported as occurring in this state.

The American Medico-Surgical Bulletin, beginning with the New Year, will be issued as a semi-monthly, with Dr. R. G. Eccles of Brooklyn, in editorial charge. The annual subscription has been reduced from four dollars to one dollar, and the policy of the publication will be upon radically different lines from those heretofore pursued by its retiring editors. It would appear to the interested inside observer that the "brilliant editorials, straight from the shoulder, written without fear or favor," and the greatly extolled "campaign against medical humbugs of every kind" in which other journals were invited to follow the *Bulletin's* lead to a glorious medical Arcady, has not been attended by the scintillating success that the projectors anticipated.

CORRESPONDENCE.

THE MEDICAL NEWS ANTITOXIN INVESTIGATION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: I desire to offer my very earnest commendation on the investigations undertaken by the MEDICAL NEWS to determine the strength of the different preparations of diphtheria antitoxin that are now on sale in different parts of this country.

It would seem almost unnecessary to direct attention to the fact that the value of a preparation of antitoxic serum depends not upon the bulk of the serum, but upon the antitoxin contents; and yet this matter of supreme importance in determining the efficacy of diphtheria antitoxic serum has received comparatively little attention outside of France and Germany, where the tests are under governmental control. In Great Britain, until within a few months, it was unusual for preparations of serum to bear any statement of their strength in antitoxin. They were simply labeled diphtheria antitoxin, or antitoxic serum, dose 10, 20, or 30 c.c., as the case might be.

The investigations of the special commission of the London *Lancet*, made during the recent summer, showed conclusively that many of the preparations in use in England were entirely inefficient, or almost without value. I had occasion at that time to direct a communication to the editor of the *Lancet*, calling attention to the action of the New York Health Department in December, 1894, regulating the sale of this agent in this city. On December 26th, 1894, a communication by Dr. T. Mitchell Prudden and the writer was addressed to the New York City Board of Health recommending "that the Board take such action as may be required to prohibit the sale or exposure for sale in this city of any preparation of this remedy in which the vial containing it does not bear a label giving the value in antitoxin of the contents, as measured by some recognized standard." As the result of this recommendation the Health Board adopted an amendment to the Sanitary Code on January 9th, 1895, reading as follows:—"Sec. 220—That no preparation of diphtheria antitoxin shall be offered or exposed for sale in this city unless the receptacle containing such preparation bear a label on which is placed the name and the address of the producer, and upon such label, or upon a circular accompanying such receptacle and enclosed with it in a sealed package, shall be printed or written the date of production and the value of the contents in antitoxin, as measured by some generally recognized standard."

At the time that this action was taken there were already on sale in this city two or three preparations of so-called antitoxic serum, which contained absolutely no antitoxin and these preparations were being sold at $5 to $10 a vial. The action of the Board taken at the very beginning of the work in this country resulted in the immediate disappearance of all the absolutely spurious preparations from this city, and had, I believe, a most beneficial influence throughout the country, in causing the various producers of antitoxin to label their preparations in such form as make possible the exact determination of their antitoxin contents. Unfortunately, however, the systematic testing of such preparations cannot well be placed under governmental control in this country, and the public and profession are somewhat at the mercy of the producers.

The Massachusetts State Board of Health has undertaken from time to time to make and publish reports of tests of preparations of antitoxin on sale in Massachusetts, and the Pennsylvania State Board of Health has taken similar action. The New York City Health Department has, also, from time to time tested preparations of anti-

toxin on sale in this city, and where preparations were below the standard marked on the label have notified producers of the fact and warned them to withdraw such preparations from sale in the future.

The action of such a representative journal as the MEDICAL NEWS, in undertaking to make tests of all the preparations largely in use in this country, will have a most salutary influence upon the character of the serum which is being produced. All of the reputable producers, who are anxious to send out serum only of the best quality—of which I am glad to say there are a number in this country—will gladly welcome such investigations, and those who are not reputable, will be forced to discontinue the production of serums of poor quality.

Of course it is not possible to determine with absolute chemical accuracy the strength of preparations of diphtheria antitoxin, and of course it is understood that there is some loss in antitoxic power with time; but the approximate determination of the value of any preparation is simple, well understood, and sufficiently accurate for the purpose required.

Sincerely yours,

HERMANN M. BIGGS.

NEW YORK, December 22, 1896.

THE MEDICAL NEWS ANTITOXIN INVESTIGATION.

To the Editor of THE MEDICAL NEWS.

DEAR SIR: Your report of the experimental investigation into the strength of the different preparations of antitoxin sold in this country is interesting and instructive reading. The medical profession is certainly under great obligation to the NEWS for taking up this question, and I sincerely hope that you are not going to let the matter drop. You have started on a good work; by all means continue it.

I think you are right in saying that what the profession wants is not antitoxin which can be furnished for a low price, but one which is absolutely reliable and that the profession and the public are willing to pay whatever it will cost to produce such an article.

Very truly yours,

L. EMMETT HOLT.

NEW YORK, December 19, 1896.

OUR PHILADELPHIA LETTER.

[From our Special Correspondent.]

MEETING OF THE PATHOLOGICAL SOCIETY.—DR. SKENE OF BROOKLYN READS A PAPER BEFORE THE GYNECOLOGICAL SECTION OF THE COLLEGE OF PHYSICIANS.—MEDICAL DINNERS AND FESTIVITIES, ETC.

PHILADELPHIA, December 19, 1896.

AT the last meeting of the Pathological Society, the specimens presented were so exceptionally interesting that it is a difficult matter to discriminate between them. Dr. H. W. Cattell brought forward a new and rapid method for the preparation of frozen sections, by methyl and ethyl chlorid. The specimen to be cut is prepared as usual and placed on a cork and a stream from a reservoir containing a combination of these drugs, known as anestile, is allowed to play on it from thirty seconds to a minute. As soon as crystals of ice are seen forming on the specimen, it is found to be firmly adherent to the cork, ready for use, and can be cut into sections as desired. The simplicity of the method, together with its rapid action and comparatively small cost, should soon gain a place for it in popular favor.

Dr. J. P. Arnold presented the kidneys from a case of primary interstitial nephritis without arterial change, in a young man. The etiological factor in this case seemed to be the point of especial interest. The kidneys were almost entirely devoid of secreting substance. The interstitial structure being in great preponderance. The usual factors in the production of such a condition were eliminated by the history of the case, the final solution suggested by Dr. Arnold being, that the condition was a congenital one finding its analogy, for instance, in the condition of the thyroid gland in some cases of cretinism. Dr. F. A. Packard reviewed a case of aneurism of the abdominal aorta, showing the specimen and dwelling particularly upon the fact that it had ruptured into the pleural cavity, a very rare occurrence in aneurisms in the locality mentioned. Among other specimens exhibited was one of perforating tuberculous ulcers of the intestine, by Dr. S. Solis-Cohen, who regarded the perforation of the bowel in such cases as a very rare complication of the disease.

At a recent meeting of the Gynecological Section of the College of Physicians Dr. Alexander J. C. Skene read a very able and interesting paper on the diagnosis and treatment of disease of the pelvic viscera in women. Drs. Baldy, Noble, and Howard Kelly discussed it in their usually skilful manner. After the meeting Dr. Skene and the other guests of the evening were tendered a reception at the University Club.

During the last few weeks there have been accounts in the secular press of the investigations ordered by Judge Gordon as to the detention of prisoners presumably insane in the Eastern Penitentiary in this city. The investigation is now being made by the grand jury, and some light may be thrown on the comparative influence and worth of the cellular or solitary confinement system as against the aggregate or commingling method.

This is the season for the interchange of social amenities over the festive board, and numerous have been the banquets and entertainments within the past few weeks. Notable among them was the dinner given to Honorable William Potter, the recently elected President of the Board of Trustees of Jefferson Medical College. Dr. A. K. Minich presided in his own inimitable manner, and toasts were ably and eloquently responded to by Judge S. Gustine Thomson, William Singerly, Esq., Drs. S. Weir Mitchell, J. Chalmers Da Costa, and W. M. L. Coplin. The fiftieth anniversary of the Northern Medical Society of this city was celebrated by a banquet at the Hotel Walton. Dr. Richard H. Townsend, the only one of the charter members of the organization still living, was unable to be present and sent a letter of regret which was read at the meeting.

SPECIAL ARTICLE.

THE USE OF ANTITOXIC SERUM IN THE TREATMENT OF DIPHTHERIA UNDER THE SUPERVISION OF THE NEW YORK CITY HEALTH DEPARTMENT, WITH A RESUME OF THE PUBLISHED REPORTS ON THIS SUBJECT.

BY HERMANN M. BIGGS, M.D.,
OF NEW YORK;
PATHOLOGIST AND DIRECTOR OF THE BACTERIOLOGICAL LABORATORIES, NEW YORK HEALTH DEPARTMENT,
AND
ARTHUR R. GUERARD, M.D.,
OF NEW YORK;
ASSISTANT BACTERIOLOGIST.

(Continued from page 715.)

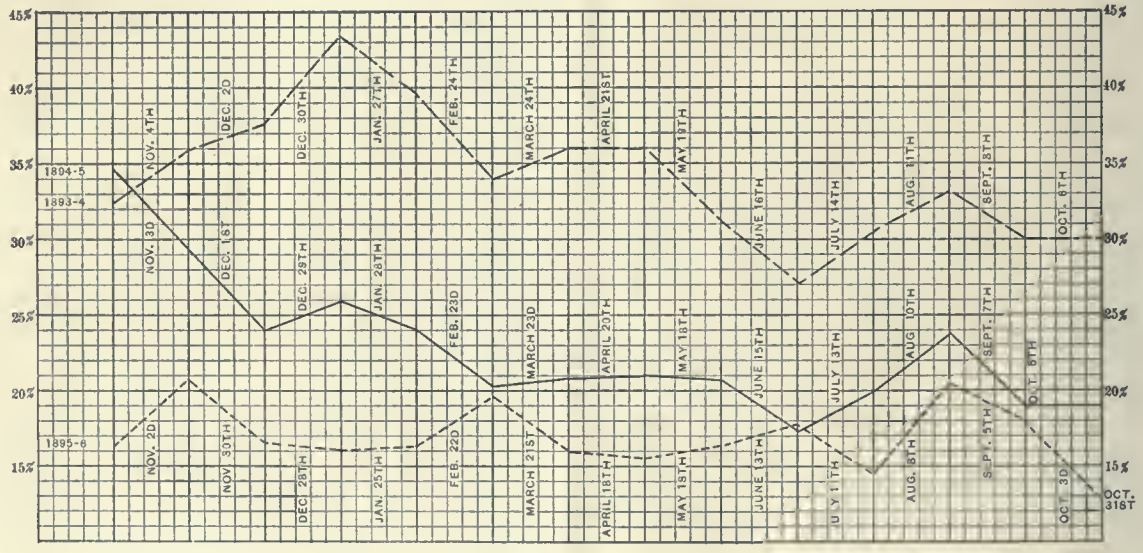
Before considering these figures, and those in other tables relating to New York, it should be stated that antitoxin was first introduced to a very limited extent from abroad in November, 1894. In January, 1895, the distribution and use of the antitoxin produced by the New York Health Department was begun, the amounts used and distributed, of both the foreign and domestic products, increasing gradually until the fall, when a very rapid expansion in the use of antitoxin took place, as indicated by the large increase in its sale, its free distribution to the physicians of the city, and its free administration by the medical inspectors of this Department.

Proceeding now to the consideration of the figures in table 8, we note that the percentage of mortality from diphtheria and croup in 1895 (19.1 per cent.) is much lower than that for any previous year, even when compared with the percentage of mortality from *diphtheria alone*. The lowest rate prior to 1895 is that for 1889, 25.9 per cent., which, for reasons previously given, is certainly too low. It is also to be noted that the decrease in mortality from 1894 to 1895 is considerable, amounting to over thirty-five per cent. of the rate for 1894. In the sixteen years for which the figures are given, the greatest previous increase or decrease in case fatality for any year as compared with that preceding it, is in 1887, when the decrease amounted to twenty-five per cent. of the rate for 1886, or twelve per cent. less than the percentage decrease, 1894 to 1895. But in this year (1887) the decrease in death-rate is accompanied by an increase of 361 in the number of deaths, while in 1895 there is a decrease of 894 in the absolute mortality as compared with that of 1894. This large actual and relative decrease in case fatality in 1895 points to the introduction in this year of some previously non-existent factor.

Proceeding next to a comparison of total cases with total deaths, there is indicated an apparent tendency toward correspondence of deaths and cases as to increase or decrease. To this there are several exceptions, as will be seen by an examination of the figures. From 1890 to 1894, however, with the exception of a small decrease in the number of cases in 1892 as compared with the previous year, there is a steady and rapid increase in both cases and deaths until 1895, when this correspondence is abruptly destroyed, a very large decrease in deaths taking place, while the number of cases is increased by 712, making the total of cases for 1895 the largest ever recorded in the city. The introduction of some disturbing factor, previously non-existent, is thus again strongly indicated.

Chart No. 1[1] gives the case fatality from diphtheria and croup in New York for periods of four weeks, the figures for

CHART NO. 1.



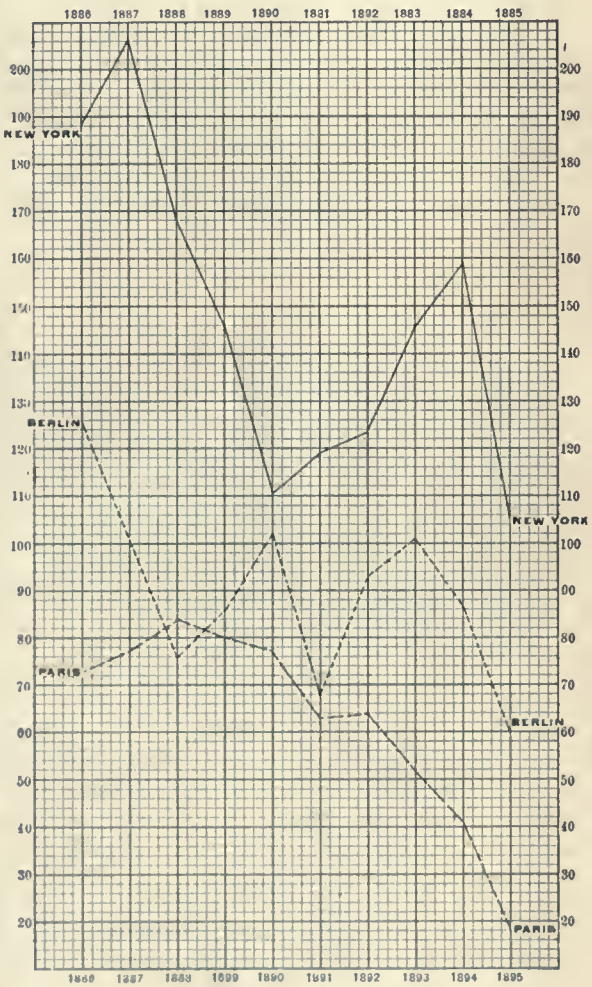
New York. Diphtheria and Croup. Case fatality, periods of four weeks. November, 1893, to October, 1896.

[1] The tables containing the data from which this and subsequent charts presented have been constructed, are omitted for the sake of brevity.

cases and deaths on which it is based being taken from the weekly reports of the Health Department. The method of bacteriological examination in the diagnosis of diphtheria was inaugurated by the Department in May, 1893, and by the autumn of that year had been very generally adopted by the medical profession, and entirely so by this Department through its medical inspectors, as an efficient adjunct to clinical diagnosis. It has been claimed that a considerable increase in reported cases of mild diphtheria, with a consequent decrease in case fatality, results from the extended use of bacteriological examinations in this disease. This claim is not substantiated by a careful comparison, recently made in this office, of the clinical diagnosis with the results of bacteriological examination in cases of suspected diphtheria; but supposing it to be true, any variation in case fatality so produced would in all probability have been relatively the same in the period selected for comparison, previous to the introduction of antitoxin (*i. e.*, November, 1893, to November, 1894), as in the corresponding periods after its use had been begun. The influence of this factor may therefore be almost entirely disregarded. Considering the chart we note, in the year previous to the introduction of antitoxin, an increase of case fatality from 32.3 per cent. in November to a maximum of 43.3 per cent. in January, followed by a decrease to a minimum of 27.1 per cent. in July. With the exception of a slight decrease in October, 1894, the case fatality increases from July to November. At this point, coincident with the introduction of antitoxin, a decrease begins, continuing steadily, with the exception of a slight rise in January, to March, 1895. This is in sharp contrast with the figures for the corresponding period of the previous year. From March to June, 1895, the rate remains practically constant, declining to a minimum of 17.2 per cent. in July. The usual seasonal increase in case fatality then begins, but in October, at which period began the rapid extension in the use of antitoxin previously noted, a decrease begins, which, with the exception of comparatively small increases in November, 1895, and March, 1896, and a somewhat marked rise in August, 1896, has continued to date of writing (November, 1896). The case fatality for October (12.8 per cent.) is the lowest ever recorded for a corresponding period in New York. The rise in August (from 14.4 per cent. for July to 20.6 per cent.) is undoubtedly due, in large measure, to the protracted period of extreme heat, which occurred in the early part of this month, and which produced the highest general mortality recorded in this city for many years. It is interesting to note that the usual seasonal decrease in actual cases and deaths during the late summer and early autumn, followed by an increase on the advent of colder weather, and the opening of the public schools, occurred both before and after the introduction of antitoxin, being apparently uninfluenced by this, and bearing, as a rule, no direct relation to the changes in case fatality recorded.

Chart No. 2 gives the case fatality in diphtheria and croup for periods of four weeks in New York and Paris, and for diphtheria only (croup not separately reported) in Berlin. Cases of croup are not separately reported in the statistics of the latter city. The figures for cases and deaths are taken from weekly reports of the three cities, and for New York correspond with those presented in a portion of chart No. 1. In Paris, antitoxin was in general use in January, 1895, the beginning of the period tabulated, and was largely used in Berlin, while in New York it had just been introduced. The gradual approximation of the case fatality in New York to that in Paris and Berlin is well shown in the chart, and coincides with the increasing use of antitoxin in the former city. In Berlin, climatic influences appear to have but little, if any, effect in increasing or diminishing the number of actual cases and deaths. The effect on case fatality is, however, more apparent, as the lowest rate for 1895 (12.1 per cent.) occurs in July. In Paris, the seasonal variations coincide quite closely with those in New York for 1894, the lowest case fatality and smallest number of deaths occurring in July, and the smallest number of cases in October. The remarkably low case fatality in Paris is of special interest. In July, 1895, it reached the extraordinarily low figure of

CHART NO. 2.



Berlin, Paris, New York. Diphtheria and Croup. Number of deaths per 100,000 of population, 1886–1895.

4.8 per cent., while the highest record-rate (May, 1896) is but 15.9 per cent.

Chart No. 3 gives the number of deaths from diphtheria and croup, per 100,000 of population, in Berlin, Paris, and New York, from 1886 to 1895. In all three cities the ratio of deaths to population is lower in 1895, and the decrease from the ratio of the preceding year greater, than for any previous year, with the exception of Berlin, where the decrease of ratio from 1890 to 1891 is greater than that from 1894 to 1895. In Paris and Berlin, the actual number of deaths, independent of the population, is lower than for any previous year—in Paris most markedly so, less than one-half that of the lowest previous annual mortality (that of 1894), when antitoxin was already in use. In New York the decrease from the ratio of 1894 is in excess of any change in previous years, the decrease being thirty-three per cent. of the ratio of 1894, as compared with a decrease from 1889 to 1890 of twenty-four per cent. of the ratio of 1889, the largest previous change.

Tables 9 and 10 give the deaths from diphtheria and croup, in Paris and Berlin respectively, from January, 1889, to June, 1895, inclusive, by months. The remarkable decrease in mortality in Paris, coincident with the introduction of antitoxin, is well shown, the number of deaths per month falling off rapidly from June, 1894, while the annual mortality for 1895 exhibits a large decrease from previous years, being but forty-four per cent. of that in 1894, which is itself lower than that for any previous year, back to 1886, the figures before this date not being at command. In the week ending September 19, 1896, with eighty-five cases reported during this and the previous week, not a single death occurred from diphtheria or croup in the city of Paris.

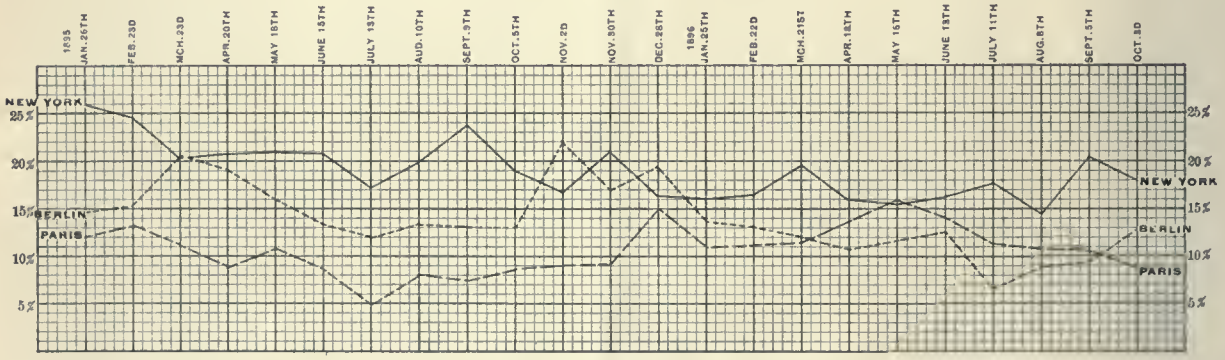
Table 11 gives the case fatality from diphtheria and croup in the Paris hospitals by months, quarters, and years, 1893 to 1895, inclusive, with a portion of 1896. Antitoxin was introduced into some of the hospitals some time in advance of its employment in the city at large (it having been used somewhat during June, July, and August, 1894, and generally, after September). The reduction in case fatality subsequent to its introduction is extraordinary. The lowest rate recorded in 1893 is for October (thirty-seven per cent.), while in 1894, prior to the introduction of antitoxin, the lowest rate is that for February (forty-seven per cent.). As compared with these, the highest rate in 1895 and 1896 is that for December, 1895 (19.7 per cent.). The quarterly and yearly statistics are equally striking. The lowest rate for 1893 and 1894, before the general use of antitoxin, is that for the third quarter of 1894 (forty per cent.), at which time antitoxin was already in use to a considerable extent, while the highest subsequent rate is that for the second quarter of 1896 (seventeen per cent.). For the year 1895, the rate reaches the extraordinarily low figure of 13.6 per cent., as compared with 51.4 per cent. for 1893, 50.3 per cent. for the first three quarters of 1894, and 35.5 per cent. for the year (one-quarter year, antitoxin in use).

Here, as in all other tables presented, the case fatality rapidly decreases with the introduction and increasing use of antitoxin, although in each of the three cities, this took place at a time when the case fatality is normally on the increase with the advent of cold weather.

Table 12 presents statistics for the Berlin hospitals similar to those given for Paris in table 7. They are unfortunately incomplete, no figures for 1894 being at command, and for 1893 the annual figures only. A comparison of the case fatality for 1893 with that for 1895 is, however, entirely confirmatory of the figures previously considered. The rate for 1893 is forty-four per cent.; that for 1895, 15.7 per cent.

Considering as a whole the facts and figures presented above, we observe that a large and rapid decrease in the absolute number of deaths from diphtheria and croup has taken place at certain times in three cities, of varying climatic conditions and different nationalities, in which these diseases are endemic. An extraordinary decrease in the case fatality from these diseases has also occurred, and this fatality has not subsequently risen to any extent in a period of some twenty-two months, and is now, in New York, far lower than at any period in the previous twenty-two years. This decrease did not take place at the same time in each of these cities. It occurred in New York some months later than in Berlin, and in Berlin some months later than in Paris. It has, however, occurred

CHART NO. 3.



New York, Paris. Diphtheria and Croup. Berlin. Diphtheria, only. Case fatality, periods of four weeks. 1895–1896.

in all three cities at a period of the year when, from the history of former years, an increase in the mortality would be expected. The reduction in mortality has occurred in hospital practice as well as throughout the cities at large. It seems evident that some influence, hitherto inoperative, must have come into action to produce the results outlined above. Upon investigation, it appears that all of the results described have followed closely upon the introduction of diphtheria antitoxin, and have become more marked in close coincidence with its increasing use as a remedy for the treatment of diphtheria. The conclusion seems therefore inevitable that we owe to antitoxin the remarkable decrease noted in the mortality from diphtheria and croup.

(The Berlin hospital statistics for 1894 are not available.)

NOTE.—The case fatalities for both Berlin and Paris hospitals are calculated on the sum of the total cases discharged by death or recovery during each month, quarter, or year. The number of cases admitted during and remaining in hospital at the end of each month, quarter or year is not given in the statistics.

The following *résumé* of the statistics and reports on the antitoxin treatment of diphtheria begins with the first extensive application of the new remedy in the early part of 1894, and brings the subject as nearly as possible up to date (October 1, 1896).

In reviewing the reports which have been published in the various medical journals of the Continent of Europe, Great Britain, and the United States, such a mass of material has been found that it has been no easy matter to sift and condense it in such a way as to make it available for the purpose desired.

Several collective investigations of the antitoxin treatment of diphtheria have already been published in Germany and this country by Heubner, Monti, Eulenberg, Crandall, Foster, Welch, the *Kaiserliches Gesundheitsamt* in Berlin and others; and though in making these investigations the whole field has been carefully gone over, there has been no hesitation in following the paths which others have marked out. Special acknowledgment of obligation for assistance, however, is due to Welch's most admirable article on the subject.

It is hoped that such a compilation of the results obtained by a large number of the best scientific and clinical observers in all parts of the world, from a thorough trial of antitoxin for a period extending over two years, may be of use and interest, not only in demonstrating the value of the remedy, but also in inducing a still more extended application of what may now be confidently affirmed to be a specific against one of the most terrible diseases with which we have to deal.

The first report of experiments made with the blood serum of immunized animals was communicated by Behring and Wernicke to the Seventh International Congress of Hygiene and Demography, held in London, August, 1891. In 1892 these authors published a second article describing more fully the principles of serum-therapy as applied to diphtheria. The earliest report of cases treated with antitoxin was in 1893, and consisted of thirty cases of diphtheria treated by Behring in the Institute for Infectious Diseases in Berlin. At this time the serum employed was very weak in antitoxin, but later, Behring and Ehrlich succeeded in obtaining a stronger serum (though for some time the serum did not have the strength which is now considered to be necessary for curative purposes). In April, 1894, 233 cases of diphtheria treated in the Berlin Hospitals, with a mortality of twenty-three per cent., were reported by Ehrlich, Kossel, and Wassermann. Dr. Otto Katz reported to the Berlin Medical Society on June 27, 1894, the results of the antitoxin treatment of 128 cases from March 14, 1894, in Professor Baginsky's service in the *Kaiser und Kaiserin Friederich Kinder-Krankenhaus* in Berlin. The serum used in these cases was Aronsons' serum obtained from horses. A few weeks later Baginsky reported 163 cases in all with a mortality of 12.9 per cent. Several reports now appeared of similar results obtained during the latter part of 1893 and the first part of 1894.

It remained, however, for Roux to arouse the interest of the world in the discovery which Behring had announced three years before. His masterly address delivered at the Eighth International Congress of Hygiene and Demography held in Budapest, September, 1894, in which he gave a clear and forcible description of his experiments and results in the treatment of 300 cases of diphtheria with antitoxin in the *Hôpital des Enfants Malades* in Paris, really directed the attention of the whole medical profession to this subject, and with this may be said to have begun the first extensive application of the new treatment for diphtheria.

In reviewing the subject of the antitoxin treatment of diphtheria it will be found that its value has been tested chiefly in two ways: the first is by a study of statistics which show the absolute mortality in cities and hospitals before and since the introduction of antitoxin and the comparative mortality of series of cases treated by antitoxin with that of similar series treated previously, or simultaneously, in other ways; the other is by the clinical method, the observation of the effect of antitoxin upon the course of the disease.

All statistics are open to fallacies owing to varying factors and conditions. The age of the patient is a most important factor in determining the mortality in diphtheria, either with or without the use of antitoxin, and unless the age is stated, the statistics are of little value.

Different methods of diagnosis may also lead to errors in the conclusions. The diagnosis of the cases treated by antitoxin has been usually verified by bacteriological examination, whereas in former times the diagnosis was mostly clinical. A bacteriological examination enables us now to exclude from our statistics many cases of angina which would formerly have been included. These cases are less severe than cases of true diphtheria, and on this account the statistics of mortality in the older reports are lower than they should be. On the other hand, a bacteriological examination often enables us to recognize as diphtheria mild cases of angina, which in former days would not have been included in diphtheria statistics. It is not likely, however, that among hospital patients the number in this class is as large as in the other. Experience, moreover, has shown that the cases, which on bacteriological examination have proved to be true diphtheria, when subjected to the former methods of treatment have given the highest mortality.

Another question to be considered is the severity of the epidemic. This not infrequently varies in different times and places. The only way to avoid the fallacy thus arising is to take a large number of cases for comparison occurring in widely separated places and over an extended period of time, and to compare cases treated with and without antitoxin at the same time and in the same place.

Again, it is maintained by some that the low rate of mortality in diphtheria, which has been ascribed by its advocates to the antitoxin treatment, is due to a large increase in the number of cases, a milder type of the disease being now received into the hospitals, owing to the early treatment recommended under the new method, while formerly only the severest cases were brought for treatment. This is possibly true to a certain extent in some hospitals, but it does not account for the great difference in the total mortality between the old and the new treatment; then, too, many cases are now excluded, as all

cases admitted into the hospitals are bacteriologically diagnosed and treated only with antitoxin when found to be true diphtheria, and the remaining cases if not brought for early treatment would frequently have developed into severe or fatal cases.

Regarding the value of the evidence as to the efficacy of the remedy based on clinical study, this, of course, depends upon the confidence we place in the opinions formed by the individual observers. But when the opinions, expressed by many of the best clinical observers in Germany, Austria, France, England, and America, etc., are almost unanimously in favor of it; and when we consider that the majority of these men, if not absolutely opposed to the new treatment, were very timid and cautious in adopting it, and have reached their conclusions only after the most convincing proofs based on practical results, it would seem that there were no longer any reasonable grounds for refusing to accept the opinion of the vast majority.

It remains now to present a series of statistical tables showing the results of the antitoxin treatment up to the present time. The statistics contain all the larger series of cases which have been reported up to date (omitting the statistics of the New York Board of Health, which are given separately), which it has been possible to find in the library of the Academy of Medicine. The list is not complete, as no single or isolated cases have been taken, only series of cases of ten and over. There has been no selection of cases, and no reduplication so far as known, certainly none that could be avoided.

The results obtained by different observers naturally vary somewhat, taken as they are from so many different sources treated under such varying conditions, and with such different preparations of antitoxin, and yet, on the whole, the apparent unanimity is all the more remarkable on this very account, and proves that the total results arrived at are reasonably true and conclusive. Admitting all possible accidental errors which may have arisen—and it is simply preposterous to assume that intentional errors have been committed by scientific observers in every part of the world—the fact remains that in over 24,000 cases of diphtheria treated with antitoxin, which have been reported, the mortality has been apparently reduced by fully fifty per cent.

Summaries of the various tables, prepared from the collected reports follow:

TABLE I.—MORTALITY OF CASES OF DIPHTHERIA TREATED WITH ANTITOXIN AND PREVIOUS OR SIMULTANEOUS PERCENTAGE OF MORTALITY WITHOUT ANTITOXIN.

This table gives the number of cases treated with antitoxin, the number and percentage of deaths, and the previous or simultaneous percentage of mortality without antitoxin, contained in 158 reports of larger series of cases, in hospital and private practice. These cases include not only those which, in the early use of antitoxin, were given insufficient doses, but also the cases which were moribund at the time of the first injection or died within twenty-four hours after it.

In a total of 24,768 cases treated with antitoxin, there were 4004 deaths, or an average mortality of sixteen per cent. The following is a summary of the results obtained in hospital and private practice:

SUMMARY OF TABLE I.

	Cases.	Deaths.	Mortality, per cent.	Previous Mortality, per cent.
In 109 reports from hospital practice	15,560	3009	19.0	30 to 40
In 49 reports from private practice	9208	995	10.1	
Total in 158 reports	24,768	4004	16.0	30 to 40.0

In 109 reports from hospitals, there were 15,560 cases, with 3009 deaths, or a mortality of 19 per cent. with the antitoxin treatment; in 49 reports from private practice, there were 9208 cases, with 995 deaths, or a mortality of 10.1 per cent., or, in a total of 24,768 cases, there were 4004 deaths, a mortality of 16 per cent., as against a previous or simultaneous mortality of 30 to 40 per cent. (taking the lowest figures in the reports) without antitoxin.

It would appear, therefore, according to these reports, that there has been a reduction of mortality in diphtheria, in both hospital and private practice, of at least fifty per cent., as the result of the antitoxin treatment. The lower percentage of mortality in private practice is probably due to the fact that the patients usually come under treatment in an earlier stage of the disease, and are generally more favorable cases.

TABLE II. MORTALITY OF CASES OF DIPHTHERIA TREATED WITH AND WITHOUT ANTITOXIN.

This table gives the number of cases (taking the reports which show these data) treated *with* and *without* antitoxin, and the percentage of mortality. These cases were treated simultaneously or during intervals of forced interruption of the antitoxin treatment, or in the periods immediately before and after the antitoxin treatment.

SUMMARY OF TABLE II.

	Cases.	Deaths.	Mortality, per cent.
Hospital cases with antitoxin	7986	1754	21.0
Hospital cases, without antitoxin	9939	3309	36.4
Private cases, with antitoxin	3161	412	13.0
Private cases, without antitoxin	4255	1717	40.0
Total in 45 reports, with antitoxin	11,147	2169	19.1
Total in 45 reports, without antitoxin	13,294	5026	37.8

From 45 reports in which these cases were recorded it appears that there were 11,147 cases treated *with* antitoxin, resulting in 2169 deaths, or a mortality of 19.1 per cent.; while at the same time, or during the period immediately before or after the antitoxin treatment, there

were 13,294 cases treated *without* antitoxin, with 5026 deaths, or a mortality of 37.8 per cent.

Separating the hospital and private cases there were treated in hospital 7986 cases *with* antitoxin, with a mortality of 21 per cent., as against 9039 cases treated *without* antitoxin, with a mortality of 36.4 per cent. In private practice there were 3161 cases treated *with* antitoxin, resulting in a mortality of 13 per cent., as against 4255 cases treated *without* antitoxin, with a mortality of 40 per cent.

Thus put to the severest test, selecting only the worst cases, as was often done intentionally for purposes of control, and to determine the value of the new remedy (though occasionally it was an unfortunate necessity, owing to the lack of antitoxin, as some reports show, which compelled a forced interruption of the antitoxin treatment) there is still a difference of 50 per cent. in favor of the antitoxin treatment. Surely no effect of climate, or season, or "genius epidemicus," or any of the various theories brought forward by the opponents of antitoxin, can explain the difference in these results. Some other and more powerful factor than any or all of these was evidently at work to produce such a striking contrast in the practical results from two modes of treatment applied at the same time, or under identically the same conditions, by so many different observers.

Some of the details of the most striking of these groups of cases which were treated *with* and *without* antitoxin at the same time, or during intervals of forced interruption, may be tabulated as follows (the full table will be published elsewhere):

TABLE III.

	With Antitoxin.			Without Antitoxin.		
	Cases.	Deaths.	Per cent.	Cases.	Deaths.	Per cent.
1. Hospital d. Enfants Maladies, Paris....	300	78	26.0	....	....	....
2. Hospital Trousseau, Paris	....	....	....	520	316	60.0
3. Hospital Franz Joseph.....	110	14	12.7	144	62	43.0
4. Unterholzner.....	37	8	25.8	36	24	66.0
5. Epidemic, Triest...	321	56	17.1	427	213	50.0
6. Kaiser and Kaiserin Friederich Hospital, Baginsky.....	303	39	13.2	230	70	47.8
7. Vucetig.....	30	2	6.6	30	6	20.0
8. Austrian statistics..	1128	149	13.2	1849	704	38.1
9. Rauchfuss (Russia).	34	7	21.0	30	16	52.0
10. V. Engel.....	39	10	25.5	62	31	50.0
11. Charité Hos., Berlin	299	53	16.7	....	....	....
12. Bethany Hos., B'rlin	....	....	....	249	12	43.1
13. Blumenfeld.....	229	20	8.7	48	11	23.6
Totals	2930	436	14.9	3625	1455	40.0

In a total of 2930 cases treated *with* antitoxin, 436 died, giving a mortality of 14.9 per cent., while of 3625 cases treated *without* antitoxin at the same time, or during intervals of forced interruption (owing to lack of antitoxin) 1455 died, a mortality of 40 per cent.

EXPLANATORY NOTES REGARDING THE STATISTICS IN TABLE NO. III.

Roux reports 300 cases treated with antitoxin in the *Hôpital des Enfants Malades* (1) in Paris with a mortality of 26 per cent, at the same time that 520 cases were treated without antitoxin in the *Hôpital Trousseau* (2) with a mortality of 60 per cent. The previous mortality in these hospitals had been about the same; the time, the type of the disease, every condition was the same, except the mode of treatment, and the resulting mortality.

Ganghofner reports 110 cases treated with antitoxin in the *Franz Josef Clinic* (3) in Prague with a mortality of 12.7 per cent, while during an interval of forced interruption in the same hospital, owing to the supply of antitoxin having run out, 144 cases were treated without antitoxin with a mortality of 43 per cent.

Unterholzner (4) in the *Leopoldstadt Hospital* in Vienna records the results in 37 cases with antitoxin in which the mortality was 25.8 per cent., and 36 cases without antitoxin during an interruption of the antitoxin treatment, in which the mortality was 66 per cent.

During an epidemic of malignant diphtheria in the districts of Triest (5) and Bukowina, the Austrian Health Department sent out a supply of antitoxin to be used among the people. Before the antitoxin arrived the mortality had been fearful in these districts. Three hundred and twenty-one cases were treated with antitoxin with a mortality of 17 per cent. The supply of antitoxin sent was insufficient to furnish the whole section in which the epidemic was raging. Four hundred and twenty-seven cases were treated without antitoxin, and the mortality among these was 50 per cent.

Baginsky (6) records a most striking illustration of the effects of antitoxin in the *Kaiser und Kaiserin Friedrich Kinder-Krankenhaus* in Berlin—a result so striking that it converted Professor Virchow, who, up to that time, had been an opponent of the new treatment. In eight weeks in this hospital 63 cases had been treated with antitoxin with a mortality of less than 13 per cent. Suddenly the supply of serum gave out, as unfortunately the horse from which the serum had been taken died. The old methods were resorted to, and during the next seven weeks, 109 cases were treated without antitoxin with 55 deaths, or a mortality of over 50 per cent. This increase in the mortality induced the hospital authorities to return to the use of the serum. Immediately there was a change. In the next six weeks 84 cases were treated with a mortality of less than 15 per cent. The total figures are given in the table.

In speaking of this remarkable experience Professor Virchow said "All theoretical considerations must give way to the brute force of these figures, and I consider it the duty of every physician to use a remedy giving such clinical results."

Baginsky, in commenting on this circumstance, says: "It is all the more remarkable, as the ratio of mortality of those treated with the serum, before and after the period of interruption varied within very small limits. If one will permit figures to speak at all, there has scarcely been made on human beings a more demon-

strative test of the curative power of a therapeutic agent. It was an experiment forced upon us, but it proved to us how terrible was the form of disease which we were treating, and how numerous would have been the victims without the use of the healing serum."

Professor Virchow again reiterated his opinion in a report which was read on the antitoxin treatment of diphtheria in the same hospital, on December 25, 1895, when he said, that from April to November of that year 303 cases out of 335 treated had recovered, the mortality which had formerly been 43 per cent. having decreased to 9½ per cent.

Vucetig (7) reports two groups of cases of 30 each, one treated with antitoxin and the other with Loeffler's solution; the antitoxin cases gave a mortality of 6.6 per cent., the others a mortality of 20 per cent.

According to the official records of the Austrian Health Department, (8) there were treated during the month of February (1896) in all Austria 1128 cases with antitoxin with a mortality of 13.2 per cent., whereas 1849 cases which were treated without antitoxin at the same time gave a mortality of 38 per cent.

Rauchfuss (9) reports 34 cases treated in hospital with a mortality of 21 per cent., and 30 control cases treated at the same time without antitoxin with a mortality of 52 per cent.

Von Engel (10) in Bohemia reports 39 cases treated with antitoxin with a mortality of 25.5 per cent., and 62 cases treated at the same time without antitoxin with a mortality of 50 per cent. The antitoxin cases, in these reports, are said to have been unusually severe and therefore taken as a test of the new remedy.

Heubner (11) reports 299 cases treated with antitoxin in the *Hôpital Charite* in Berlin with a mortality of 16.7 per cent., and 249 cases treated in the Bethany Hospital (12) at the same time under the same conditions of age, season, etc., without antitoxin with a mortality of 43 per cent.

Blumenfeld (13) reports 229 cases treated in private practice with antitoxin with a mortality of 8.7 per cent., and 48 cases not treated with antitoxin, because they were considered to be *too mild*; the mortality among the "mild cases" was 23.6 per cent. as against 8.7 per cent. among the apparently severer cases treated with antitoxin.

Many examples of the same kind might be cited from the published reports, fuller details of which will be found in the Bulletin of the Health Department, but from these it may be seen that the antitoxin treatment has stood the test of comparison with other approved methods of treatment, whenever the contrast has been decidedly drawn.

KOSSEL'S STATISTICS OF REDUCTION IN THE ABSOLUTE MORTALITY FROM DIPHTHERIA AND CROUP.

It has been maintained by some in criticizing the statistics of the antitoxin treatment, that the reduction of the death-rate, as shown by the mortality percentage, proves nothing, if at the same time there has been an increase in the number of cases reported, as the reduced mortality rate may have been due to the milder character of the cases treated; and that the only convincing figures are those which show, not a reduction of *percentage* mortality, but of *absolute* mortality.

Kossel has undertaken to satisfy this *desideratum* in the following statistics:

I.—In the *Hôpital Charite* in Berlin there were admitted during the years 1886 to 1893–94, an annual average of 146 diphtheria patients, of whom 78, on the average, died; in 1894–95 and 1895–96, 285 were admitted, of whom 40 died. The absolute mortality, therefore, during the serum period (1894–95 and 1895–96) was reduced to one-half of the average for the previous eight years, though the number of cases admitted had increased two-fold.

II.—THERE WERE REPORTED IN ALL THE BERLIN HOSPITALS THE FOLLOWING CASES AND DEATHS FROM DIPHTHERIA DURING THE ELEVEN YEARS, 1885–1896:

Year.	Cases.	Deaths.
1885	1928	789
1886	1738	609
1887	1636	589
1888	1446	523
1889	1623	573
1890	1792	695
1891	1764	623
1892	2074	837
1893	2450	951
1894	2890	801
1895	3061	484

It appears from these statistics that in the Berlin hospitals, as a whole, the deaths have been reduced one-half since the introduction of antitoxin, though the number of cases reported has steadily increased. The statistics for 1896 show a still larger reduction in the absolute and case mortality.

III.—THE FOLLOWING TABLE GIVES THE CASES AND DEATHS REPORTED IN BERLIN AND THE DEATHS IN PARIS (CASES NOT REPORTED PREVIOUS TO 1894) FROM 1886 TO 1896:

Year.	Berlin.		Paris.
	Cases.	Deaths.	Deaths.
1886	6968	1662	1524
1887	5438	1392	1564
1888	4190	1195	1718
1889	4220	1210	1706
1890	4586	1601	1639
1891	3504	1342	1363
1892	3683	1637	1398
1893	4315	1416	1262
1894	5220	1321	993
1895	6106	987	411

According to these figures the mortality from diphtheria rose and fell in Berlin, corresponding more or less closely to the number of cases reported up to the year 1894. In 1894 and 1895 the cases increase in number, while the absolute mortality declines, and in Paris, in 1895, it decreases to less than one-third of the previous average. The statistics for Berlin for 1896 (see previous tables) show an equal reduction. Antitoxin was more lowly introduced there than in Paris.

IV.—THE ABSOLUTE MORTALITY AND DEATHS PER 100,000 POPULATION IN ALL GERMAN CITIES OF OVER 15,000 INHABITANTS, FROM 1886–1895:

Year.	Absolute Mortality.	Deaths per 100,000.
1886	12,211	124
1887	10,970	107
1888	10,142	96
889	11,919	108
890	11,915	105
1891	10,484	84
1892	12,365	97
1893	16,557	130
1894	13,790	101
1895	7611	53

Average from 1886 to 1894, 106.

This table shows a steady rise in absolute mortality up to 1894, when there was a moderate reduction, followed by a very great reduction in 1895, when antitoxin was generally used in the German cities. The sudden fall in the absolute mortality from diphtheria amounts to one-half the average of the previous nine years.

V.—MONOD, THE DIRECTOR OF THE PUBLIC HEALTH DEPARTMENT OF FRANCE, HAS GIVEN THE AVERAGE ABSOLUTE MORTALITY FROM DIPHTHERIA PER MONTH FOR THE FIRST SIX MONTHS OF EACH YEAR FROM 1888 TO 1895, AND FOR 1895, IN ALL FRENCH CITIES OF OVER 20,000 POPULATION:

Month.	1888–1895.	1895.
January	469	205
February	466	187
March	499	155
April	442	160
May	417	113
June	334	84
Totals	2,627	904

The Pasteur Institute in Paris began the distribution of antitoxin in November, 1894. Early in 1895 arrangements were made to furnish antitoxin free to those who were unable to pay for it. In 108 cities of over 20,000 inhabitants, with an aggregate population of 8,150,000, the average number of deaths from diphtheria during the first six months of the seven years, 1888–1895, was 2,627. In the first six months of 1895 the absolute mortality from diphtheria in the same 108 cities was only 904. or a diminution at the rate of 65.6 per cent. The rate of diminution, month by month, went on almost uniformly from one of 56.2 per cent. for the month of January, to 75 per cent. for the month of June.

The use of antitoxin began in Paris and Berlin in the latter part of 1894, and was general in 1895; in New York antitoxin was introduced by the health department in 1895, and is only now becoming generally used.

Taking all these figures together it would seem to have been conclusively proved that, whether we estimate the percentage mortality, or whether we consider the absolute death-rates reported in hospitals or cities as a whole, there has been a marked and sudden reduction in mortality from diphtheria since the introduction of antitoxin. To what else should this be attributed if not to the effects of the antitoxin treatment? It would be a strange coincidence, indeed, which produced by natural causes such a diminution in the death-rate of a disease that had continued unchanged, within slight variation, for many successive years, and then dropped to one-half during the period corresponding to the use of antitoxin, if it were not due to the improved method of treatment.

VI.—FROM STATISTICS TAKEN FROM THE OFFICIAL RECORDS OF BERLIN, PARIS, AND NEW YORK, ON FILE IN THE OFFICES OF THE NEW YORK HEALTH DEPARTMENT, THE FOLLOWING DEATH-RATES FROM DIPHTHERIA AND CROUP, ESTIMATED PER 100,000 POPULATION, ARE GIVEN:

ABSOLUTE DEATH-RATE PER 100,000 POPULATION.

Year.	Berlin.	Paris.	New York.
1886	125.7	73.2	187.5
1887	100.7	76.9	206.6
1888	76.1	83.7	167.7
1889	85.6	79.9	146.2
1890	102.0	77.5	110.6
1891	67.5	63.0	118.7
1892	92.9	63.6	123.3
1893	100.8	51.4	145.5
1894	86.7	40.7	158.5
1895	59.7	17.7	105.2
1896	30.9	17.5	91.3

TABLE IV.—COLLECTIVE INVESTIGATIONS.

This table has been prepared in order to compare the results noted in the present report, with the collective investigations of other observers. It gives the total results reported of the antitoxin treatment, and the previous mortality without antitoxin, in twelve collective investigations, published in Germany, Austria, Japan, and the United States. It is seen, by a comparison of these reports, that each and all of them record almost exactly the same results, *viz.*, that the mortality from diphtheria has apparently been reduced.

TABLE IV.—COLLECTIVE INVESTIGATIONS OF OTHER OBSERVERS OF THE SAME OR SIMILAR CASES TREATED WITH ANTITOXIN, AND PREVIOUSLY, WITHOUT ANTITOXIN.

Reporter.	Treated with Antitoxin			Treated previously or without Antitoxin: Mortality, per cent.
	Cases.	Deaths.	Mortality, per cent.	
Heubner, Berlin	3036	625	20.6	38 to 40.0
Monti, Vienna	3888	716	18.4	.....
Crandall, St. Louis	2632	442	16.8	42.0
Forster, Washington	2740	509	18.5	45.3
Eulenburg and Schwalbe, Berlin	5833	559	9.6	14.7
Welch, Baltimore	7166	1239	17.3	42.0
Kaiserl. Gesundh. Amt. (Berlin):				
First quarter 1895	2228	386	17.3	.....
Second quarter 1895	2130	306	14.3	26.7

Present report to October, 1896.	24,768	4004	16.0	30 to 40.0

It would thus appear from this table that twelve different observers, analyzing the same or similar cases treated with antitoxin, have arrived at identically the same result, *viz.*, that the mortality of diphtheria, according to the published reports, has been reduced at least one-half as the effect of the antitoxin treatment; the average mortality for the antitoxin cases being sixteen per cent., including hospital and private practice, and thirty to forty per cent. for the cases treated previously or without antitoxin. There is naturally in this table, in many instances, a reduplication of cases; they are put together merely to show the uniformity of the results of the collective investigations.

There is a reduction of at least one-half, as the effect of the antitoxin treatment, the average mortality for the antitoxin cases being sixteen per cent., including hospital and private practice, and thirty to forty per cent. for the cases treated previously or without antitoxin.

TABLE V.—MORTALITY OF OPERATIVE AND NON-OPERATIVE CASES OF DIPHTHERIA TREATED WITH ANTITOXIN.

One of the most significant effects of the antitoxin treatment of diphtheria, and that which affords the best proof of its value, is shown in the remarkable results, which have been obtained in cases of laryngeal diphtheria with stenosis, which include the severest and most fatal forms of the disease.

This table gives the cases, deaths, and percentage of mortality in operative and non-operative cases of diphtheria treated with antitoxin as compared with the previous or simultaneous mortality in operative cases without antitoxin.

SUMMARY OF TABLE V.

	Total Cases Treated.			Non-operative Cases.			Operative Cases.			
	Cases.	Deaths.	Mortality, per cent.	Cases.	Deaths.	Mortality, per cent.	Cases.	Deaths.	Mortality, per cent.	Previous Mortality, per cent.
Total in 72 reports..	15,148	2626	16.6	12,066	1491	13.5	3082	1135	36.7	70.0

Of the 3082 operative cases 1355 were tracheotomized, resulting in 569 deaths, or a mortality of 42 per cent.; 1173 cases were intubated with 361 deaths, or a mortality of 30.8 per cent.; 52 cases intubated required secondary tracheotomy, of which 37 died, or 71 per cent.; 502 cases required tracheotomy or intubation (it was not stated which) with 168 deaths, or a mortality of 33.2 per cent.

According to a report of 12.736 cases up to 1887 published by Monti, the mortality in tracheotomy previously was 73.3 per cent. Hirsch gives from statistics collected in von Bergmann's clinic the average previous mortality in tracheotomy cases for the last ten years up to July, 1894, at 68.5 per cent. Of 5546 intubation cases collected by McNaughton and Maddren[1] (1892) the previous mortality was 69.5 per cent. Brown has shown since somewhat better results in intubation, *viz.*, a mortality of 51.6 per cent.

[1] Collective Investigation of the American Ped. Soc., July, 1896.

In a total of 15,148 cases treated with antitoxin in this table taken from 72 reports, there were 2626 deaths, or a mortality of 16.6 per cent.; of these 12.066 cases were not operated on, (80 per cent.) of which 1491 died, giving a mortality of 13.5 per cent.; 3082 were operated on, intubation or tracheotomy, of which 1135 died, or 36.7 per cent. Before the antitoxin treatment 40 per cent. of all cases are reported generally as having required operation, and the previous mortality was 70 per cent. for all operated cases, according to the average figures recorded in these reports.

But taking the lowest average recorded at all in any reports, *viz.*, 68.5 per cent. as the previous mortality in tracheotomy cases, and 51.6 per cent as the previous mortality in intubated cases, and the contrast in these figures and those obtained under the antitoxin treatment is sufficiently evident. Here again, in operative cases of the severest forms of the disease the mortality seems to have been reduced by nearly fifty per cent. as the result of the antitoxin treatment; while at the same time the number of cases requiring operative interference has decreased to one-half. This last effect of the serum treatment is due to the fact that many cases of beginning laryngeal stenosis are relieved after injection, without having recourse to operation, few or no cases, which were free of laryngeal obstruction when the antitoxin was injected, being reported as having developed such symptoms later.

TABLE VI.—MORTALITY OF CASES TREATED WITH ANTITOXIN ARRANGED ACCORDING TO AGE.

As age is an important factor in estimating the value of any treatment of diphtheria, these statistics have been collected from all the reports in which the age was mentioned, and arranged in the form of a table. The reports of age mortality, however, have not been uniformly or systematically recorded; but the main features of the table may be summarized as follows:

SUMMARY OF TABLE VI.

Age.	Cases.	Deaths.	Mortality, per cent.
0–2 Years.....	1494	469	31.4
2–5 "	3678	762	20.7
5–10 "	3184	473	14.8
Over 10 Years.....	1444	99	6.9

Comparing these results with those obtained previously or without antitoxin the following have been reported:

Herz: Mortality, per cent.	Hirsch: Mortality, per cent.	Baginsky: Mortality, per cent.
0–1 Year 80.0	0–1 Year.....88.3	0–2 Years.....63.3
1–3 " 45.0	1–3 " 82.5	2–4 " 52.8
3–5 " 40.0	3–4 " 63.9	4–6 " 37.9
5–10 " 17.0	4–5 " 46.9	6–10 " 24.6
Over 10 Years...17.0	6–7 " 43.2	10–15 " 14.6
	Over 7 Years..22.2	

The contrast here shown of the results of treatment *with* or *without* antitoxin, arranged according to age, is sufficiently evident and needs no further comment.

TABLE VII.—MORTALITY OF CASES TREATED WITH ANTITOXIN ARRANGED ACCORDING TO THE DAY OF DISEASE ON WHICH TREATMENT WAS COMMENCED.

Behring claims that the specific curative effect of antitoxin will be the more certainly produced the sooner the treatment is commenced; and that out of 100 cases of *true diphtheria*, which are injected with a curative dose of antitoxin within forty-eight hours from the beginning of the disease, not more than five will die.

In order to test the truth of this statement, and to determine what has actually been effected by the use of the remedy, this table has been prepared, which gives the mortality of cases treated with antitoxin, arranged according to the day of the disease on which the treatment was begun. It is to be understood, as stated in all the reports, that these statistics are based in most cases upon the statements of parents or friends of the patients and may not be absolutely correct as to the exact day of the disease on which the antitoxin was administered, but they give nevertheless an average of the results obtained.

SUMMARY OF TABLE VII.

First and Second Day of Disease.			Third and Fourth Day of Disease.			After the Fourth Day.			Day Unknown.		
Cases.	Deaths.	Mortality, per cent.	Cases.	Deaths.	Mortality, per cent.	Cases.	Deaths.	Mortality, per cent.	Cases.	Deaths.	Mortality, per cent.
4232	267	6.3	3870	656	17.2	1984	685	34.6	339	44	13.0

Or, taking only those reports in which the day of disease on which treatment was commenced is more specifically stated, we have:

	Cases.	Deaths.	Mortality, per cent.
First day of disease.....	1415	51	3.5
Second day of disease....	2640	213	8.0
Third " "	2340	300	12.8
Fourth " "	1458	346	23.6
Fifth day and after.....	1912	671	35.0
Totals.....	9765	1581	16.1

According to these statistics it is apparent that by far the best results are obtained when treatment is commenced early in the disease, if possible within the first forty-eight hours, and not later than the third day; that after the third day the mortality increases rapidly, and that after the fifth day comparatively little benefit is derived from the use of antitoxin, though it should always be administered.

Considering the fact that in all these statistics are included the cases which were moribund at the time of the first injection, or which died within twenty-four hours after, there would seem to be very good reason to believe with Behring, Kossel, Roux, and other observers, that every fresh case of true pharyngeal diphtheria can be cured by the timely administration of an adequate dose of antitoxin, and that the claim, that only five per cent. of the cases injected within the first forty-eight hours of the disease would die, has actually been substantiated.

TABLE VIII.—IMMUNIZATION BY ANTITOXIN.

The question of immunization now comes up for consideration, and though but comparatively few complete statistics on this subject have been published, yet the prophylactive treatment of diphtheria is a matter of so great importance that this table has been prepared to show in how far (according to the reports already published) the administration of immunizing doses of antitoxin has resulted in protecting those exposed to infection. The data are incomplete and unsatisfactory, not only from the fact that many cases immunized have not been reported, but also because many reported as immunized have received insufficient doses of antitoxin; but such as they are the results are interesting as showing the complete protection apparently afforded to many persons exposed to the disease.

SUMMARY OF TABLE VIII.

Number of Cases Immunized.	Number of Antitoxin Units Injected.	Number of those Immunized Attacked Within 30 Days.	Number of those Immunized Attacked After 30 Days.
17,516	50 to 1000 (Average, 150 to 200).	109 mild, 1 fatal.	20 mild, 1 fatal.

According to thirty-five published reports, of which this is a summary, there are 17,516 persons, children and adults, to whom immunizing injections of antitoxin have been given, with the result that, though exposed to infection from diphtheria in families and institutions, and during epidemics when the disease was raging, only 131 of those immunized were attacked later, and of these 129 were mildly affected (109 within thirty days, and 20 after a month), and recovered; while only 2 died of the disease, one within and the other after thirty days from the time of injection. The two fatal cases probably received far too small doses to produce immunity, or the diphtheria was complicated with other diseases not mentioned. The mild cases all recovered, in some a repetition of the injection being given. Only some slight and temporary ill effects are described as having occasionally resulted from the immunizing injections, though in the *Hôpital des Enfants Malades* and the *Hôpital Trousseau* in Paris, and in Löhr's experiments, full curative doses were often given to healthy subjects. Rashes, joint-pains, and other transient effects of the antitoxin serum were occasionally observed, but no serious after effects which could be ascribed to the action of the antitoxin, or which would contra-indicate its use.

The prophylactive dose of antitoxin is now thought by most observers to be from 150 to 500 antitoxin units. The duration of immunity after injection has not been definitely determined, and undoubtedly varies. Some hold the opinion that it lasts only one or two weeks, others

that it extends over thirty days and more. Four weeks may probably be considered as the average duration.

NOTE.—The complete tables, of which these are only the summaries, will shortly be published, with a full report of the cases, in a scientific bulletin of the New York Health Department. They are omitted here, as they are too bulky for such an article.

The statistics given have been collected from reports of series of cases of diphtheria treated with antitoxin, published up to October 1, 1896, in the various medical journals of the world—Germany, France, England, Austria, Italy, Russia, Switzerland, Denmark, Australia, Japan, etc., and America,—accessible in the Library of the New York Academy of Medicine.

CONCLUSIONS.

We desire to bring out strongly and clearly the fact that it matters not from what point of view the subject is regarded, if the evidence now at command is properly weighed, but one conclusion is, or can be reached, whether we consider the percentage of mortality from diphtheria and croup in cities as a whole, or in hospitals, or in private practice; or whether we take the absolute mortality for all the cities of Germany whose population is over 15,000, and all the cities of France whose population is over 20,000 (in France and Germany antitoxin has been more generally employed than elsewhere); or the absolute mortality for New York City, or for the great hospitals in France, Germany, and Austria; or whether we consider only the most fatal cases of diphtheria—the laryngeal and operative cases; or whether we study the question with relation to the day of the disease on which treatment is commenced, or the age of the patient treated; it matters not how the subject is regarded or how it is turned for the purpose of comparison with previous results, the conclusion reached is always the same, namely, there has been an average reduction of mortality from the use of antitoxin in the treatment of diphtheria of not less than fifty per cent., and under the most favorable conditions a reduction to one-quarter, or even less, of the previous death-rate. This has occurred not in one city at one particular time, but in many cities, in different countries, at different seasons of the year, and always in conjunction with the introduction of antitoxic serum, and proportionate to the extent of its use.

Then, finally, there is to be added not only the experimental proof of the specific action of antitoxin in neutralizing the toxin of diphtheria, but also the overwhelming mass of evidence derived from the personal observations of the most distinguished practitioners of medicine of every country. There are to-day, in the whole civilized world not more than three or four active opponents of the antitoxin treatment of diphtheria, whose names were known to the medical profession before the introduction of antitoxin.

It is well to bear in mind the fact, that what is called conservatism in medicine is often only a cloak assumed to cover up indolence. The acceptance of a new principle, or a new fact, involves the expenditure of a certain amount of mental energy. Old ideas and conceptions must be discarded or readjusted to the new information acquired. This involves labor and effort, which some are not willing to expend. They are not willing to go over the data at hand and form conclusions for themselves, but shake their heads wisely, predict a reaction, and plead for conservatism. It is not possible now for any unprejudiced person to master the evidence available regarding the value of antitoxin in the treatment of diphtheria, and reach anything but a positive conclusion.

The deductions to be drawn from a review of these statistics and reports presented would seem to be self-evident and conclusive. The value of antitoxin in diphtheria is no longer a question of opinion or theory, but an established fact. "*Proberin geht ueber studerin*," those who have had the largest experience with the remedy, and have most thoroughly tested its merits, are most in favor of it. The few who oppose it have proved nothing in comparison with the enormous mass of evidence as to its specific value,

It may, therefore, be affirmed that the following facts have been demonstrated:

1. That diphtheria antitoxin, where generally employed, has reduced the mortality from diphtheria at least one-half.

2. That it has a distinctly favorable effect on the clinical course of the disease, shortening it and lessening its severity.

3. That the earlier the treatment is commenced the better the results obtained; the mortality, when adequate doses of antitoxin have been given with the first forty-eight hours of the disease, not exceeding five per cent.

4. That antitoxin is a specific against true diphtheria, (*i. e.*, where the symptoms are due solely to the Klebs-Loeffler bacillus) and is less efficacious in mixed infectious, but even in these forms of diphtheria is of decided benefit.

5. That it is not necessary to wait for a confirmatory bacteriological diagnosis, but that in every clinically suspicious case of membranous angina, especially in children, a medium dose of antitoxin should immediately be given, and repeated if required by the further developments of the case.

6. That antitoxic serum is a remedy without serious after-effects in the doses which have ordinarily been employed (the after-effects, such as rashes, etc., being insignificant in comparison with the danger of the disease); that it has no injurious action on the kidneys, the heart, or the nervous system; that it does not entirely prevent albuminuria, heart failure, and post-diphtheritic paralysis, because the effects of the diphtheritic toxin which has already entered the system before the administration of the remedy, no matter how soon the treatment is begun, are not always completely counteracted by the antitoxin, though there is every reason to believe that in sufficient doses it does prevent any farther extension of the toxic action after its affects have been produced.

7. That the protection conferred by immunizing doses of antitoxin is almost absolute for a short period of time, *e.g.*, three or four weeks, when a sufficient number of antitoxin units is administered, and that with a high grade preparation, where only small quantities of serum are re-

quired, the remedy is absolutely harmless even with the youngest infants.

8. That antitoxin, if not a specific cure for all forms of diphtheria occurring in the human subject, is by far the best remedy for the treatment of the disease.

To the critics of the antitoxin treatment I may repeat the words of a famous German poet, quoted by Professor Soltman:

> "Das ist die richtigste Kritik von der Welt,
> Wenn neben das was ihm missfällt,
> Einer etwas Ergens and Besseres stellt."

Or, in other words:

> "The best critics in the world are they
> Who along with that which they gainsay,
> Suggest another and a better way."

REVIEWS.

A Treatise on Obstetrics. For Students and Practitioners. By Edward P. Davis, A.M., M.D., Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic; Clinical Professor of Obstetrics in the Jefferson Medical College, Philadelphia, Etc., Etc. Illustrated with 217 engravings and 30 plates in colors and monochrome. Lea Brothers & Co., Publishers, Philadelphia and New York. 1896.

The aim of the author in writing this treatise on obstetrics is, as he states, "to furnish to the student a text-book, and to the practitioner a work of reference." Generally speaking, he has attained his object admirably, as far as the practitioner is concerned, for, from a practical standpoint, the work is all that could be desired, being concise, non-theoretical, and written in a style that appeals strongly to the active practitioner; but as a text-book for the student of medicine the book is entirely too advanced. Theories in theoretical midwifery are entirely ignored. There is no descriptive anatomy of the female organs, from an obstetric standpoint, for the benefit of the student, nor is the pelvis considered as a whole. There is no mention of the mechanism of labor, and this, it must be admitted, is the essential sub-subject, the study of which fits one to be a good obstetrician. I fail to note the usual method of approaching the subject of midwifery, so admirably shown in other text-books of this kind, which gradually leads the student up to that point where he can comprehend what is meant by midwifery, and what is expected of the obstetrician.

The book is divided into sections, the first relating to Pregnancy and Labor, the second to the Pathology of Labor, the third to Obstetrical Operations, and the other four to Abortion, Extra-uterine Pregnancy and the Puerperal State, the Infant in Health and Disease, and the Jurisprudence of Obstetrics. The first section treats of pregnancy and labor in a masterly way, and when it has been read there can be no doubt of what the author wishes to impress upon the mind of his reader. Objection can be taken only to that part relating to the differential diagnosis of albuminuria and the toxemia of pregnancy. This difference is well nigh impossible to distinguish, and if it were, is of no practical importance, since the prophylaxis and treatment, both medical and surgical, are the same in both. Then the Walcher position is incorrectly described, it being one of extreme extension, the hips at the edge of the bed or table, and the lower extremities hanging free, and not, as the author describes it, "the thighs extended and allowed to fall downward, resting either on the floor or on a couple of chairs."

The next section comprises an exceptionally complete treatise on the subject of pathology and labor, and includes an excellent description of pelvic deformities, and of the methods of pelvimetry. Stress is laid upon the fact that too much reliance should not be placed upon the pelvimetric measurements in deciding upon the period of inducing labor; it is more wise to rely upon the adaptability of the fetal head to the pelvic inlet, and if, by suprapubic pressure engagement fails to occur in cases of relative or absolute pelvic contraction, he deems it expedient to bring about delivery. The subject of accidental hemorrhage is exhaustively treated here, as well as elsewhere in the book.

The chapter on Forceps is the best in the book, and follows the most recent teaching. Axis-traction in appropriate cases is generally advised, but not by the ordinary axis-traction instruments, the more complicated adjustment of tapes, through fenestræ of the blades, being preferred. The illustrations accompanying this chapter are remarkably good, the photographs having evidently been taken at the bedside. The plate showing the application of the forceps high up in the pelvis, however, is not to be commended, as it shows the forceps guided by two fingers only, whereas the whole hand should be introduced into the vagina. There is no reason why ether should be recommended in forceps operations, and chloroform in versions. A typographical error appears on page 330; "cervix" should read "vertex."

The chapters on Version, Symphysiotomy, and Celiohysterectomy are admirable, and must be read in order to be appreciated.

Abortion, Extra-uterine Pregnancy, and the Puerperal State comprise the next section. It is a mistake to introduce a description of gynecological operations in a book on midwifery, for, though dependent upon obstetrics, they are fully treated of in works devoted to this branch. It is questionable, too, if the chapters devoted to the Infant in Health and Disease were wisely added. The duties of the *accoucheur* proper cease when the puerperal period ends, and this subject rightly belongs to a treatise on the diseases of children, rather than to one on obstetrics.

It is a surprise and gratification, however, to read the section devoted to the Jurisprudence of Obstetrics, and the author has shown excellent judgment in including it in his book. This branch has been greatly neglected by other writers, and he is to be congratulated upon having brought his labors to a close in such a masterful fashion.

Whatever unfavorable criticism is made of Dr. Davis' book in this instance is completely overshadowed by the genuine worth of his effort to give to the medical profession a thoroughly scientific and brilliant treatise on obstetrics. No one is infallible, and, even though the author were, the reviewer cannot always agree with his expressed views.
